Dietary practices among vegetarians are highly variable. Most vegetarians are at little or no risk of dietary inadequacy from their eating patterns and do not merit special assessment although they may benefit from general dietary advice adopted to their eating preferences. For example, neither a man who regards himself as a semi-vegetarian (also referred to as a meat avoider) because he avoids red meat most of the time nor a lacto-ovo vegetarian woman with no other major dietary avoidances are unlikely to need further dietary assessment.

Some characteristics of sound and adequate vegetarian diet patterns include the following:

- Limited animal food avoidances, only sporadic avoidances, or abstinence rather than complete animal food avoidance.
- Consumption of a wide variety of animal food groups and a wide variety of foods within each group.
- Use of a nutritionally sound food guide for diet planning; sound vegan, and vegetarian food guides are available that ensure that nutrient needs are adequate, balanced, and moderate
- Regular use of foods fortified with nutrients likely to fall short in the diet and vitamin or mineral supplements in RDA or Daily Reference Value (DRV) amounts to meet nutrient needs plus use of a nutritionally sound food guide if the individual follows a vegan pattern, or has multiple food avoidances.
- Membership in a group (such as Seventh Day Adventists) or family with a long tradition of adherence to healthy vegetarian eating styles and attitudes toward health.

Possibly Inadequate Vegetarian Dietary Patterns

For vegetarians who are likely to be at high risk of dietary inadequacy, further and more complete dietary assessment and planning may be needed. The entire pattern of intake (including avoidances, substitutions and additions of foods, and use of dietary supplements) must be examined to obtain a full profile of nutrient adequacy or inadequacy. The presence or absence of other lifestyle practices with potentially beneficial health impacts (nonsmoking, abstinence from alcohol, high levels of physical activity) can also have impacts on health. Individual assessment is recommended for those at special risk in nutritionally vulnerable physiological groups (due to age, life stage (pregnancy, lactation), or illness) or because they adhere to very limited patters (such as avoiding many animal food groups (vegans) and other food groups, or have multiple other food avoidances (e.g., all 'processed' nonorganic, cooked, or canned foods, 'nonwhite' foods, and 'non-natural' foods) so that only 'whole', 'nonprocessed',

'organic' and 'natural' foods are acceptable, further limiting options for planning an acceptable diet.

Characteristics that may indicate inadequate or unbalanced vegetarian diets and the need for further assessment include:

- Entire or very extensive avoidance of animal food groups.
- Refusal to eat fortified plant foods or to use nutrient-containing dietary supplements, or processed foods.
- Refusal to eat 'processed' or 'nonorganic' foods.
- Frequent fasting, vomiting, purging, or drastically altered diet during illness.
- Lack or avoidance of conventional health and medical care (e.g., prescribed medications, vaccinations, mental, or dental health visits), use of only alternative medical care.
- Nutritional vulnerability due to age or physiological condition (infancy, weaning and toddlerhood, rapid growth, puberty, pregnancy, lactation, chronic illness, or recovery from illness, old age, frailty).
- Low weight for height, body mass index (BMI) <18.5 kg m^{-2}, >4–7 kg (10–15 lb) unintentional weight loss, or rapid unintentional weight loss of $>5\%$ in a month.
- Deeply held beliefs in alternative philosophical or religious systems that rigidly restrict food choice and prescribe vegetarian diets that fail to meet the DRIs.

Key Nutritional Concerns for Vegetarians

Of particular concern with respect to risk of inadequacy for vegetarians and especially vegans and others with extreme restrictions are energy, vitamins B_{12} and D, riboflavin, omega 3 fatty acids, calcium, iron, zinc, choline, and iodine. Vegetarians of all types can easily meet current recommendations for these nutrients if they are willing to use nutrient sources in fortified foods (such as, e.g., highly fortified cereals, calcium fortified soy milk, and juices, B_{12} fortified yeast, vitamin A fortified margarine) or specific micronutrient supplements containing enough of the micronutrient that is falling short. However, some vegetarians are unwilling to use these options, increasing risks of deficiency and making dietary planning more difficult. With respect to macronutrients, vegetarian and particularly vegan diets tend to be low in energy, total fat, saturated fat, cholesterol, and sodium. If processed foods are avoided added sugars are also low. Current recommendations for acceptable macronutrient distribution ranges (AMDR) in the US are for fat 20–55% of calories and for protein 10–35% of calories, with added sugars no more than 25% of calories, and the remainder from other carbohydrates.

Key Nutrients for Vegetarians Over the Life Cycle

Well-planned vegan and vegetarian diets can meet nutritional needs at all stages of the life cycle including pregnancy, lactation, infancy, childhood, and adolescence. There are very few longitudinal studies of individuals on the more restrictive vegetarian diets; an exception is a Dutch cohort of macrobiotic vegetarians who were followed from birth to adolescence, and who showed very poor growth and continue to have some health problems. More studies are needed so that long-lasting effects of diet early in life can be better ascertained.

Some vegetarian parents inadvertently feed their children with diets that are inadequate. The problem is not that nutritionally adequate diets cannot be planned, but that the eater's or cook's ideologies and concerns may get in the way. Under such circumstances health problems have arisen and continue to do so, especially among infants and children on vegan diets that are limited in other foods as well.

Vegan diets present more problems of micronutrient adequacy than do other vegetarian diets across the life cycle and particularly in infants and children because more food groups are eliminated, sources of vitamins B_{12}, D and bioavailable iron, calcium, and zinc may be lacking, the caloric density of the diet is lower, but bulk is higher and weaning is often very late. Vegan diets may also be low in calcium, iron, and zinc, and the forms of these minerals may not be highly bioavailable. Sources of riboflavin and choline also need to be identified.

Vegetarian infants are usually breastfed. They generally thrive until 4–6 months of age, and continue to do so if they remain at the breast and receive complementary feedings of nutritionally complete heat-treated cow's milk-based, fortified soy formulas, or other developmentally appropriate feedings that are high in nutrients, sufficient in energy, and low in bulk. Soy milk is not appropriate under 1 year of age. In countries where home prepared or commercial infant formulas and weaning foods do not provide adequate amounts of micronutrients, certain dietary supplements such as iron or vitamins B_{12} and D may be needed. Today, more fortified vegan foods are available for infants and other groups than in the past. Good food or supplemental sources of vitamin B_{12} and D (especially above approximately 40° N latitude where exposure to sunlight is not likely to be sufficient), linolenic acid (an omega 3 fatty acid to ensure that docosahexanenoic acid (DHA) intakes are satisfactory), riboflavin, calcium, and bioavailable forms of iron, and zinc must be included in the diets of weanlings and young children. Protein intakes are usually adequate if many different plant proteins are fed and energy intakes are sufficient. Growth monitoring is helpful. When soy milk is used later in childhood, especially if the child is a vegan, it should be fortified with vitamins D, B_{12}, and calcium. For children during the pubertal growth spurt, energy, calcium, iron, vitamins D and B_{12}, as well as iron are of particular concern with respect to dietary adequacy. Pregnant and lactating vegetarian women have increased nutrient needs for these and other nutrients that. can usually be dealt with by dietary planning. Elderly people who are vegetarians may have problems meeting micronutrient needs because they have low energy requirements owing to physical inactivity, whereas need for calcium, vitamin D, and vitamin B_{12} increases.

Conclusions

Vegetarian diets should be planned in accordance with the DRI or other authoritative nutritional recommendations so that they are healthful and nutritionally adequate. When vegetarian diets are unplanned, the nutrients that are likely

to fall short usually differ somewhat from those of unplanned omnivorous diets. In some cases these deficits can be easily remedied by dietary counseling. In others differences between ideologies about life, diet, and nutrient needs are such that acceptable dietary strategies are difficult. Nutrition scientists and practitioners can help vegetarians who seek their advice by screening the nutritional status of high-risk individuals, by identifying acceptable food sources of specific nutrients for the eater and when asked, by suggesting dietary modifications that may be necessary to meet individual needs when intakes fall short, and by monitoring the vegetarians' progress.

Glossary

Dark adaptation The process by which the eye, through vitamin A-enabled photoreceptor activation, adapts vision under low lit conditions, measured by electroretinography and various measures of pupillary responsiveness to light.
Visual cycle The metabolic pathway in the rod photoreceptor cells in the retina of eye that converts vitamin A into its active vitamers involved in light perception and transmitting visual images to the brain.
Vitamin A deficiency disorders (VADD) All health consequences attributable entirely or partially to vitamin A deficiency.
Vitamin A status The body's vitamin A nutriture expressed as a clinical, biochemical or functional indicator, with conventional cutoffs to convey presence and severity of deficiency. Low serum vitamin A (hyporetinolemia) is the most widely used indicator of vitamin A status (typically classified as a concentration below 0.70 μmol/l).
Xerophthalmia From xeros-dryness, -ophthalmia-pertaining to the eye. Ocular manifestations of vitamin A deficiency, including night blindness, Bitot's spots, corneal ulceration and necrosis (keratomalacia).

Introduction

Vitamin A (VA) is an essential nutrient in the human diet. As a result, deficiency can develop when its intake is chronically low, as has occurred in undernourished societies throughout human history. Its existence as a public health problem is readily manifested as eye disease. Night blindness, the mildest ocular condition of VA deficiency, has been recognized since antiquity, as depicted in bas-relief on the wall of the Egyptian pyramid in Saqqura, dating to the Middle Kingdom, and in writings of Hippocrates in the 4th century BC who recognized and treated the condition with animal liver (a major dietary source of VA). Corneal destruction and its consequent blindness, as well as milder stages of conjunctival xerophthalmia, were linked to dietary insufficiency in the eighteenth and nineteenth centuries, as cod liver oil emerged as a treatment for night blindness, 'Bitot's spots' and corneal necrosis (keratomalacia) more than a century ago. Discovery in 1913 of 'fat soluble factor A,' an ether-soluble compound in butter and egg yolk required for growth, general health, and vision in animals, ushered in the past century of vitamin discovery, advanced treatment and prevention of xerophthalmia, synthesis of VA and its analogs, understanding the vitamin's metabolic functions in the visual cycle, epithelial, immune, hematopoietic, and osteoid cell function and its avertable public health importance.

VA Deficiency Disorders (VADD)

VA is essential to maintain normal retinal function, and in regulating cellular proliferation, differentiation, and energy utilization. Effects of deficiency are most readily observed in rapidly dividing, bipotential cells such as epithelial linings of the body. These regulatory roles give rise to specific effects of hypovitaminosis A that include disturbed photoreceptor function that can lead to night blindness, metaplasia, and keratinization of mucosal surfaces that lead to conjunctival and corneal xerosis as well as epidermoid metaplasia and mucociliary defects throughout the respiratory, genitourinary, and gastrointestinal tracts as well as glandular ducts. Embryo-fetal deficiency may impair multiple organs, including the lungs and cardiovasculature, that is only beginning to emerge as a public health concern. Postnatal VA deficiency may impair development and functioning of innate and adaptive arms of the immune system that can weaken or render less-controlled complex host defenses against infection, thereby increasing severity, clinical morbidity, and risk of death. Collectively, all pathophysiological consequences attributed in varying degrees

to VA depletion are termed 'Vitamin A Deficiency Disorders' or VADD (**Figure 1**).

Biochemical Depletion

Tissue depletion of VA, while not a disorder per se, likely precedes functional consequences of deficiency. In uncomplicated hypovitaminosis A, plasma retinol tends to be homoeostatically controlled until body (primarily liver) stores become lower after which the plasma retinol concentration declines. Plasma retinol may also decrease in response to chronic inflammation and clinically significant infection, in parallel with raised concentrations of positive acute phase proteins, increased tissue VA delivery, reduced hepatic mobilization via retinol-binding protein, and increased urinary loss. Plasma retinol gradually normalizes during recovery from infection in the presence of adequate hepatic stores. If VA is deficient, imposed infection can leave the host more tissue-depleted and at-risk. Despite nondietary influences, plasma or serum retinol measurement remains the most common biochemical index of VA status. VA deficiency is generally diagnosed at a serum retinol concentration below 0.70 μmol l^{-1} (or 20 μg dl^{-1}), below which often 20% to >50% of concentrations lie in a VA-deficient population, compared to <3% in well-nourished societies. A serum retinol level <0.35 μmol l^{-1} (10 μg dl^{-1}) indicates severe deficiency. Decrements in serum retinol below these cutoffs can be expected to increase the severity of xerophthalmia and infectious illness. Other indices of tissue retinol depletion include the relative dose response, a before–after test-dose difference in serum retinol that indirectly reflects hepatic retinol adequacy, breast milk retinol concentration for assessing both maternal status and intake adequacy of breastfed infants, and stable isotopic dilution to assess the total body VA pool.

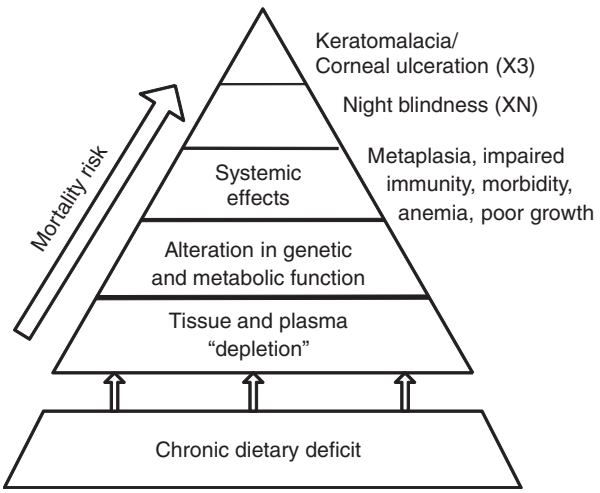

Figure 1 Concept of VADD, due primarily to underlying chronic dietary deficit in preformed VA and proVA carotenoids. Reproduced from West Jr KP (2002) Extent of vitamin A deficiency among preschool children and women of reproductive age. *Journal of Nutrition* 132: 2857S–2866S, with permission from The American Society for Nutrition.

Xerophthalmia

Conjunctival and corneal epithelia deprived of VA undergo keratinizing metaplasia. Columnar epithelial cells on the ocular surface become squamous and mucus-producing goblet cells disappear, providing the histopathologic mechanisms for deficiency-induced xerotic (drying) changes to the ocular surfaces. VA deficiency is also required for rod vision in dim light. VA deficiency-induced night blindness often occurs with histopathologic changes on the ocular surface. Thus, night blindness and clinical eye signs both are listed under one xerophthalmia classification scheme (**Table 1**).

XN and Dark Maladaptation

VA, as retinaldehyde, is an essential photosensitive pigment in rod cells of the retina that respond to light (become 'bleached') by releasing the VA ligand from the protein rhodopsin, thereby initiating neural impulses to the brain that permits vision under conditions of low illumination. The utilization and recycling of VA in this process is known as the visual (or retinoid) cycle. Hypovitaminosis A restricts rhodopsin production that, in turn, raises the scotopic (low light)

Table 1 WHO[a] Classification and minimum prevalence criteria for xerophthalmia and VA deficiency as a public health problem

Definition (code)	*Minimum prevalence (%)*	*Highest-risk period*
Children 1 to 5 years of age		
Night blindness (XN)	1.0	2–6 yr
Conjunctival xerosis (X1A)	–	–
Bitot's spots (X1B)	0.5	2–6 yr
Cornea xerosis (X2)/Corneal ulceration (X3A)/keratomalacia (X3B)	0.01	1–3 yr
Xerophthalmic corneal scar (XS)	0.05	>1 yr
Deficient serum retinol (<0.70 μmol l^{-1})	15.0	<5 yr
Pregnant/lactating women		
XN during most recent pregnancy	5.0	Third trimester
Low serum retinol (<1.05 μmol l^{-1})	20.0	Third trimester

Alpha-numeric characters in ( ) denote the WHO classification scheme for xerophthalmia.

visual threshold. Dark adaptometry is becoming possible with new field instrumentation that can detect a preclinical, lagging pupillary response to graded light intensity that can occur in a VA deficient state. Gradually, a perceptive threshold is reached that leads to recognition of XN, the earliest symptom of xerophthalmia. It is marked by an inability to move about in the dark. Young children between 1 and 5 years of age and pregnant women appear to be at greatest risk of XN. Where VA deficiency is endemic, there is often a local term for XN that translates into 'evening' or 'twilight' blindness or 'chicken eyes' (which lack rod cells and also cannot see at night), making the condition readily detectable by history. Typically, gestational XN resolves spontaneously with child birth and expulsion of the placenta, likely related to the lessening of maternal metabolic demands for VA.

X1A and X1B

Early xerosis of the conjunctiva can be detected by filter paper impression cytology, showing distorted, enlarged, and noncontiguous sheaths of epithelial cells, and disappearance of goblet cells. In advanced VA deficiency, confluent xerosis appears clinically as a dry, unwetable surface of the bulbar conjunctiva (X1A). The affected areas are usually overlaid with superficial white, cheesy, or foamy patches of triangular or oval shape that consist of desquamated keratin and bacteria (often the *xerosis bacillus*). These are known as X1B. They are nearly always bilateral, found temporal (and, in more advanced cases, also nasal) to the corneal limbus and are more reliably diagnosed than X1A. X1B are not blinding but are reflective of chronic moderate-to-severe systemic depletion of VA.

Corneal Xerophthalmia

Corneal xerophthalmia is manifested in severe VA deficiency. The earliest corneal lesions appear as superficial punctate defects, evident with a slit lamp, that with advanced deficiency become more numerous and concentrated. The cornea is considered xerotic (X2) when the keratopathy covers large areas of its surface rendering a hazy, nonwetable, lusterless, and irregular appearance on handlight examination. Stromal edema may be present. In more severe cases, thick, elevated X2 plaques may form. Usually both eyes are affected. X3A can be sharply demarcated, round, or oval defects that are usually shallow but may also perforate the cornea. Healed ulcers form a leukoma (scar) or adherent leukoma if the iris has plugged the perforated ulcer. Most ulcers occur peripheral to the visual axis and, thus, may not threaten central vision if treated in time. X3B refers to a full-thickness softening and necrosis of the corneal stroma that can cause protruding, opaque, yellow-to-gray lesions to form (**Figure 2**). These may reduce or slough off leaving a descemetocele following VA treatment. X3B usually impairs vision in the involved eye although the degree of visual loss depends on the location, thickness, and extent of corneal necrosis and the resultant scar. Owing to the generally malnourished and ill state of children with corneal xerophthalmia, fatality of hospitalized cases ranges from 4% to 25%.

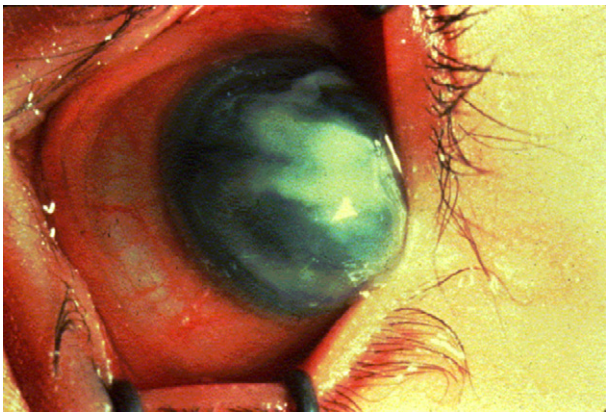

Figure 2 Keratomalacia. Reproduced from Sommer A (1995) *Vitamin A Deficiency and its Consequences: A Field Guide to Detection and Control*, 3rd edn. Geneva: World Health Organization.

Other VADD: Infection, Anemia, and Poor Growth

Infection

A synergism exists between hypovitaminosis A and infection, each exacerbating the other, representing a classic 'vicious cycle.' In this context, infection may be considered both a cause of VA deficiency and, in terms of severity and sequellae, a consequence, or 'disorder.' Xerophthalmia or severe hyporetinolemia have been consistently associated in cross-sectional assessment with higher risks of diarrhea, fever, and other infections though an acute phase reaction to infection can lower the circulating retinol level and directionality can be difficult to establish.

VA deficiency presumably raises risk of infection by compromising 'barrier' epithelial defenses and impairing regulatory innate, cell-mediated and antibody-mediated immune mechanisms. Especially, there is a growing literature implicating roles for retinoic acid in suppressing pathological and autoimmune responses to inflammation, which could underlie its role in controlling severity of infection. Epidemiological corollary evidence exists. VA-deficient South Asian preschoolers (i.e., with mild xerophthalmia) were twice as likely to develop acute respiratory infection and (in Indonesia) three times more likely to develop diarrhea over subsequent 3–6-month periods. Deficient children are also more likely to die. This was so among Indonesian preschool children whose risk of mortality rose with increased severity of mild eye signs (**Figure 3**). In Nepal, siblings of cases were more likely to develop xerophthalmia and twofold more likely to die than children living in unaffected households, reflecting a clustering of child mortality risk within VA-deficient households. Measles is an illness that can deteriorate VA status which, in malnourished children, can lead to corneal xerophthalmia, more severe complications, and increased fatality. Affecting lifelong ability is the emergence of VA deficiency in exacerbating severity of middle ear infection that may consequently increase the risk of hearing loss.

Anemia and Poor Growth

Children with xerophthalmia tend to be anemic relative to peers without eye disease. VA supplementation can often

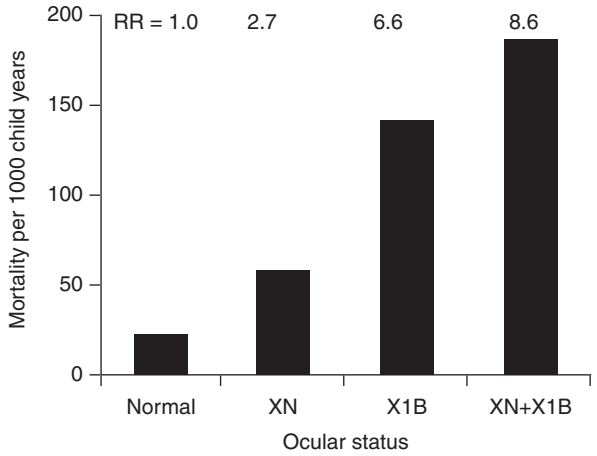

Figure 3 Risk of mortality among ~3500 Indonesian preschool children by ocular status at the outset of each 3-month interval. RR, relative risk of mortality. Adapted from Sommer A, Tarwotjo I, Hussaini G, and Susanto D (1983) Increased mortality in children with mild vitamin A deficiency. *Lancet* 2: 585–588.

improve hemotological indicators of iron status and reduce anemia. Mechanisms involved in this interaction are not clear but could involve enhanced iron absorption, storage, and transport as well as direct effects on hematopoiesis in the presence of adequate iron stores.

VA deficiency decelerates growth in animals and has been observed to be associated with both stunting and wasting malnutirition in children, possibly reflecting plausible roles for the vitamin in osteogenesis and energy metabolism. Trials, however, have shown inconsistent effects of VA supplementation on child growth, possibly due to variations in the extent of infection, seasonality in dietary protein and energy adequacy, exclusion criteria, and entry levels of VA status among study children. It appears that VA supplementation can influence ponderal and linear growth, as well as body composition, in children for whom VA deficiency is a 'growth limiting' nutritional deficit.

Epidemiology

The epidemiology of VA deficiency is mostly understood in relation to hyporetinolemia and xerophthalmia (**Table 1**), especially the noncorneal stages involving XN and X1B due to X1A. The latter eye signs may be common in the absence of effective prophylaxis, specific and likely to reflect more widespread hypovitaminosis A. Although both conditions are stages of 'mild' nonblinding xerophthalmia, they typically result from moderate-to-severe systemic VA deficiency. Preschool children and women of reproductive age are at highest risk of being VA deficient, best understood in terms of how the condition distributes by person, place, and time.

Person (High-Risk Groups)

Despite uncertainty about an appropriate cutoff for hyporetinolemia in the first months of life, infants in most poor populations are born with low VA status and, without adequate VA from breast milk and complementary foods remain deficient throughout early childhood. Current estimates suggest that VA deficiency (serum retinol $<0.70\ \mu mol\ l^{-1}$) afflicts 33%, or 190 million preschool-aged children in the developing world, of whom 5 million (~1% of all) exhibit XN. The number of extant or annually occurring cases of X1B is less well known due to few ocular surveys having been conducted since the 1990s. In one major country where recent data exist, India, an overall rate of ~1% was observed. Milder stages of xerophthalmia typically affect children beyond the first year of age, as breast milk is replaced by less nutritious food from household diet. Boys tend to be at higher risk, thereby possibly reflecting gender differences in dietary practices.

Risk corneal xerophthalmia (**Figure 2**) tends to peak in the second through fourth years of life, typically following the epidemics of acute infection such as severe measles. Informally, it appears that numbers of cases globally have dropped, likely attributable to high coverage of at-risk child populations with semiannual VA supplementation, which reduces risk of corneal disease by ~90%. A second factor has also likely been a steadily increased and sustained coverage of vaccination against measles, a major precipitant of corneal xerophthalmia.

VA deficiency has been noted to affect women living in undernourished settings, especially in relation to pregnancy, appearing to be driven by heightened nutrient demands of gestation. Globally, some 19 million pregnant women are estimated to be VA deficient (serum retinol concentration $<0.70\ \mu mol\ l^{-1}$), of whom nearly 10 million are night blind. This latter symptom not only identifies women at high risk of hyporetinemia but also anemia, wasting malnutrition, offspring mortality, and maternal morbidity and mortality (**Figure 4**). Widespread maternal VA deficiency has also been observed to coexist with HIV infection and AIDS throughout sub-Saharan Africa. However, modest, absent, or inconsistent effects of maternal VA supplementation on infant and maternal health, survival, or transmission suggest the deficiency may be more a consequence than determinant of disease severity.

Place (Geographic Clustering)

Regions of the world with the greatest burden of VA deficiency remain Southern Asia and sub-Saharan Africa which, together, account for two-thirds of all cases of mild xerophthalmia (XN) and over 75% of biochemically VA-deficient children.

The geographic distribution of VA deficiency in preschool-aged children, based on joint distributions of preschool xerophthalmia and hyporetinolemia, reflects a persistent, peri-equatorial distribution, is presented in **Figure 5**. Within a region or other locality, VA deficiency, best characterized for xerophthalmia, clusters in association with indices of underdevelopment, low availability of food sources of VA and disease patterns. In Indonesia, villages where cases of xerophthalmia were detected tended to be poorer than xerophthalmia-free communities and, within a village, cases arose more frequently from households of low socioeconomic standing than children with normal eyes (controls) (**Table 2**).

In multiple surveys in Africa and Asia preschool children incur an approximate twofold higher risk of having or developing xerophthalmia in villages where at least one other child has been diagnosed compared to villages where xerophthalmia has not been previously seen (Table 3). More striking is a 7–13-fold higher risk of xerophthalmia in siblings of cases compared to children at home with no previous history of xerophthalmia. Maternal XN and childhood xerophthalmia often coexist in households and communities. Spatial clustering seems to arise mostly from shared dietary practices at

homes and villages rather than other exposures that lead to common infections. The exception to this observation is likely to be in households and communities afflicted by HIV/AIDS.

Time (Periodicity)

Occurrence of xerophthalmia can follow predictable, though not parallel, seasonal patterns in different parts of the world. Typically, a seasonal peak in VA deficiency emerges from a convergence of causal risk factors. In South Asia, for example, a distinct peak in the incidence of mild xerophthalmia occurs during the late dry and early monsoon seasons (April–July). This peak follows a postharvest growth spurt in the cool dry season. It also coincides with a general scarcity of proVA-rich vegetables and fruits and a seasonal rise in the incidence of diarrhea, respiratory infection and measles. In this area of the world, the seasonal peak is often curbed abruptly midway through the 'mango season,' reflecting a likely impact of widespread consumption of this beta-carotene rich fruit. Periodicity, where it exists, can help identify causes and target prevention to specific times of the year.

Causal Agents (Diet and Infection)

VA deficiency results from consuming a diet that is chronically inadequate in VA in relation to need, often exacerbated by infection. A low dietary fat intake (e.g., <5% of calories) may restrict absorption of proVA carotenoids from vegetables and fruits and thus also predispose certain poor populations to deficiency.

Breastfeeding and Diet

Breast milk is an infant's most important initial dietary source of VA. Commonly, breast milk from marginally nourished mothers contains ~500 μg of retinol activity equivalents (RAE) per liter, thereby delivering 325 μg RAE per day to infants typically consuming ~650 ml day^{-1}. An 'adequate intake' of 400–500 μg RAE has been set as a dietary guide for infants, making this usual level of VA intake from breast milk marginal during the first year and, beyond infancy, marginally above an estimated deficient intake threshold of 210 μg RAE, but usually sufficient to prevent clinical signs. Studies in Asia and Africa show breastfed infants and toddlers to be 65–90% less likely to develop xerophthalmia than nonbreast-fed peers of the same age. Children who had begun weaning ~1 month earlier and completed breastfeeding ~6 months earlier than nonxerophthalmic children. Even among those breastfeeding, a higher daily frequency may confer further protection against xerophthalmia in undernourished settings.

The choice of foods offered to complement breast feeding may also affect risk of VA deficiency. Indonesian preschoolers were at a two- to sixfold higher risk of xerophthalmia if food sources of VA such as dark green leaves, mango or papaya, egg, meat or fish with liver, and milk, and other dairy products were not routinely given during the first year they were provided complementary foods, initiating a pattern that likely places children at risk throughout their early years of life. Across undernourished regions of the world, less frequent intakes of preformed VA and proVA carotenoid rich foods are observed by children with, versus absent, a history of xerophthalmia (**Figure 6**). Similar dietary differences are evident among women with versus without a history of maternal XN.

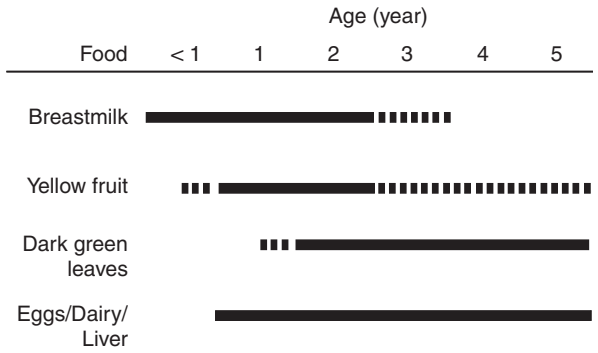

Figure 6 Foods that protect against hypovitaminosis A (xerophthalmia), based on numerous studies. Dark line, strong evidence; dashed line, suggestive evidence. Reproduced from Sommer A and West Jr KP (1996) *Vitamin A deficiency: Health, Survival and Vision*. New York: Oxford University Press.

Infection

Because a vicious cycle exists between VA deficiency and infection, infection can be viewed as a cause of deficiency. Prospective studies show that severe infections such as measles, chicken pox, diarrhea, and acute respiratory illness decrease serum as well as apparent hepatic levels of retinol and increase risk of xerophthalmia. In some settings, measles has been observed to increase by as much as >13-fold the risk of children developing corneal xerophthalmia. In Indonesia, young children with diarrhea and acute respiratory infections were twice as likely to develop mild xerophthalmia (XN or X1B) than disease-free children. Similar patterns temporal patterns between infection and XN have been observed in undernourished pregnant women. Explanations for a role of infection as a cause of VA deficiency include decreased absorption of VA, increased metabolic requirements, impaired retinol transport, greatly increased renal excretion during the acute-phase response, and slow normalization of these mechanisms coupled with a chronically decreased VA intake during extended recovery or repeated illness.

Impact of Interventions

VA deficiency can be prevented through direct supplementation, fortification of commonly eaten food items in factories or at home, or other food-based approaches that include home gardening, small animal husbandry, nutrition education, and broad agronomic approaches such as biofortifying staple crops with proVA beta-carotene. Most evaluations to date have assessed impact of supplementation and, occasionally fortification, on VA status, xerophthalmia, mortality, and morbidity.

VA Status

The impact of VA prophylaxis on status may vary by indicator, dosage, and mode of delivery of the supplement, as well as the population context, including level of initial deficiency and other risk factors. A single, high-potency supplement (210 μmol, 60 mg RAE, or 200 000 IU) has typically been shown to elevate serum retinol to near adequacy in deficiency-prone child populations for periods of up to a few months. Continuous intake of a half to full recommended allowance of VA through fortified foods gradually improves and sustains adequate serum and breast milk retinol concentrations or, when assessed by indirect means, hepatic retinol adequacy. Regular consumption of proVA food sources (dark green leaves, yellow vegetables, and fruits) has variable, though generally positive, effects on VA status. Dietary proVA carotenoid intake appears most efficacious in raising serum retinol from deficient concentrations to minimally adequate levels but often fails to optimize VA status. Variations in food matrix, methods of storage and preparation, amounts of preformed VA and fat in the diet, gut integrity and function, protein energy and VA status of the host, and genetic predisposition are among factors that may affect bioconversion to VA. Single nucleotide polymorphisms for beta-carotene monooxygenase, the enzyme responsible for cleaving beta-carotene to retinaldehyde in the VA bioconversion pathway, are beginning to be reported in populations that may help explain high interindividual variability in the bioconversion of dietary carotenoids, generally estimated to occur at ratio of 12:1 when consuming a mixed vegetarian diet.

Xerophthalmia

High-potency VA delivered to preschool children every 4–6 months, as widely practiced in low income countries, is ~90% efficacious in preventing both corneal and noncorneal xerophthalmia. Prophylactic failure (~10%) may reflect inadequacy of dosage for some children who are severely VA-deficient or become ill. Xerophthalmia, on the other hand, virtually disappears in societies consuming adequate amounts of VA-fortified foods. Supervised treatment with proVA-rich vegetables and fruit has been reported to cure or improve noncorneal xerophthalmia.

Mortality

There has been extensive investigation into the effects of VA on mortality over the past two decades in preschool-aged children, and more recently in young infants and women of reproductive age. The impact of VA supplementation on preschool child mortality has been firmly established through the conduct of eight controlled community trials in the 1980s and early 1990s specifically designed to address this outcome, involving ~165 000 children 6–72 months of age on three subcontinents (**Table 4**). In six trials, children 6 months to 6 years of age were supplemented every 4–6 months with an oral dose of VA containing 60 mg retinol equivalents (RE) (or 200 000 IU). Half this dosage was provided to children <12 months of age. One study, in India, provided a small weekly dose to children and the other, in Indonesia, supplied half of a recommended allowance of VA to children in treatment villages through a routinely marketed fortified monosodium glutamate product (a meal flavor enhancer). Rates of mortality in supplemented groups were compared to rates among children in concurrent control groups. Six of the eight trials showed reductions of 19% to 54% in preschool child mortality beyond either 6 or 12 months of age. Meta-analyses of data from these trials, alone or with additional, often smaller studies meeting inclusion criteria, have estimated the reduction in mortality to range from 23% to 34%. Cumulative

mortality curves from trials with positive results show a characteristic departure in the mortality rate of VA supplemented from control groups (**Figure 7**). Causes of death known to respond to VA include measles, diarrhea, possibly malaria, and other febrile illnesses. In particular, VA has consistently been shown to reduce fatality from severe measles, by ~50%. A lack of effect on fatality from acute lower respiratory infection has been a perplexing but consistent finding across studies.

A large dose of VA (50 000 IU), given shortly after birth, appears to reduce risk of mortality in the first half of infancy. Trials carried out to date in Indonesia, India, and Bangladesh have reported significant 64%, 22%, and 15% reductions, respectively, in infant mortality following newborn VA versus placebo receipt (Table 4), with findings from South India revealing attenuation of deaths attributed to diarrhea and fever. In contrast, two African trials, in Guinea-Bissau (Table 4) and Zimbabwe, have not reduced infant mortality, suggesting a potential mediating role of local context, including prominent infections such as human immunodeficiency virus (HIV) as was present in the latter study. Additional trials are underway in South Asia and sub-Saharan Africa. Plausible explanations for the observed impact may include maturational effects of VA on an immature immune system, gut, and airway that could enhance resistance to infection months later.

Finally, improving intake of VA, either preformed or as proVA beta-carotene in amounts approximating a recommended dietary intake, may in some settings also reduce mortality related to pregnancy where risks of deficiency and mortality are exceedingly high (e.g., ~700 or more deaths per 100 000 pregnancies). In rural Nepal, weekly VA supplementation lowered mortality related to pregnancy by 40%, largely explained by lowering severity of infections among mothers prone to XN. In contrast, large trials of similar design conducted in Ghana and Bangladesh have failed to reduce maternal mortality (Table 4), linked to lower risks of mortality and VA deficiency, reflected by improved diets in the latter two countries.

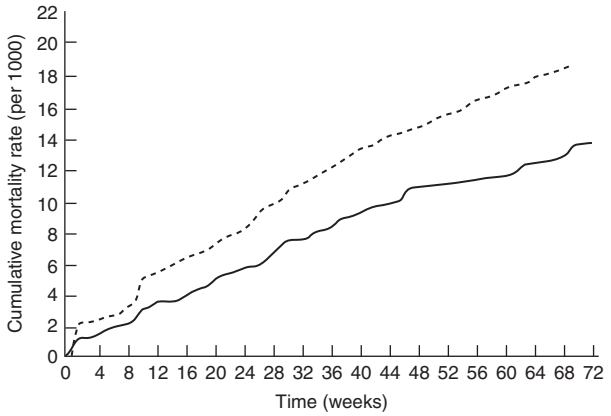

Figure 7 Cumulative mortality of children randomized to 4-monthly placebo control (dashed line) versus 200 000 IU of vitamin A (solid line) during a large community trial in Sarlahi District, rural Nepal. Reproduced from Sommer A and West Jr KP (1996) *Vitamin A Deficiency: Health, Survival and Vision*. New York: Oxford University Press.

Morbidity

Direct effects of VA on 'morbidity' have been difficult to establish, possibly due to variation in disease sensitivity to VA and inherent problems in measuring incidence, duration, and severity of morbidity in community studies. Available data suggest VA has little impact on prevalence of common childhood morbidities, but rather holds the potential to attenuate severity of infections such as measles, diarrhea, dysentery, and *falciparum* malaria. In Ghana, VA supplementation decreased childhood clinic visits for illness (relative risk (RR)=0.88), hospitalization rates for severe disease (RR=0.62) and the severity of illness among children admitted with diarrhea, compared to placebo recipients. In Brazil, prior VA receipt had no effect on children's diarrheal episodes of 1–2 days' duration (RR=0.97) but was significantly protective against episodes lasting ≥3 days with ≥4 stools per day (RR=0.91) and episodes of ≥3 day with ≥5 stools per day (RR=0.80). In an early VA trial in Sarlahi, Nepal, long term follow-up has revealed a 42% lower risk in hearing loss from middle ear infections. However, as with acute lower respiratory infection-associated mortality, multiple trials have found little effect of VA on recovery from pneumonia, a surprising finding given decades of animal experiments linking VA deficiency to keratinization and, presumably, greater susceptibility to pathogen invasion and infection, of the respiratory tract.

Management

Treatment

Children with xerophthalmia and measles should be treated immediately with oral, high-potency VA (200 000 IU) according to WHO and International Vitamin A Consultative Group (IVACG) guidelines Table 5 and provided other supportive nutritional and medical therapy, as indicated. Corneal lesions should be topically treated with a suitable antibiotic (e.g., tetracycline or chloramphenicol) to prevent bacterial infection. Corneal xerophthalmia typically improves with VA treatment within a week, and resolving within 4 weeks,

Table 5 VA treatment and prevention schedules

Age	*Treatment at diagnosis*[a]	*Prevention* *Dosage*	*Frequency*
<6 mo	50 000 IU	50 000 IU	Once within 3 day after birth[c]
6–11 mo	100 000 IU	100 000 IU	Every 4–6 months
12–59 mo	200 000 IU	200 000 IU	Every 4–6 months
Women	By severity of eye signs[b]	200 000 IU	2 doses 24 h apart # 6 weeks after delivery

[a]Treat all cases of xerophthalmia and measles on days 1 and 2; give an additional dose for xerophthalmia on day 14. For severe malnutrition give 1 dose on day 1.
[b]For women of reproductive age, give 200 000 IU only for corneal xerophthalmia on days 1, 2, and 14; for night blindness or X1B give 10 000 IU per day or 25 000 IU per week for >3 months.
[c]Based on limited number of trials in South Asia, to date, showing a ~20% reduction in infant mortality with an oral supplement given shortly after birth.
Source: Reproduced from Ross DA (2002) Recommendations for vitamin A supplementation. *Journal of Nutrition* 131: 2902S–2906S.

depending on size, thickness and location of the lesion, and nutritional and health status of the patient. XN typically disappears within 24 h of treatment. Most X1B respond within 2–5 days and disappear within 2 weeks after VA treatment, though may persist in older children. Severely wasted children should be given a single large oral dose (200 000 IU). It is also judicious to give children with severe diarrhea, dysentery, respiratory infection, and measles a single, large oral dose of VA. Large-dose VA is indicated for women of reproductive age with corneal disease. For XN, smaller daily (10 000 IU) or weekly (25 000 IU) doses are recommended for at least 3 months.

Prevention

Health consequences, or disorders, of VA deficiency can be prevented via direct supplementation of target groups, food fortification at central production facilities or by adding nutrient-dense powders to meals at home, biofortification of staple crops, and other agricultural or dietary approaches, including garden and education programs that encourage exclusive and extended breast-feeding and improved dietary quality at home.

Administration of large-dose, oral VA (200 000 IU), adjusted to age (**Table 5**), on a ~6 monthly basis is a common preventive in most undernourished societies. A half-dose is dispensed to infants 6–11 months of age and a quarter dose given to younger infants to minimize the risk of toxicity in high risk areas, although a more effective alternative to reducing infant mortality appears to lie in dosing infants shortly after birth. Periodically providing a large dose of VA helps to increase nutrient liver stores from where it is mobilized into circulation, as needed. Supplements can be provided during routine health care (e.g., for growth monitoring, immunization, and other extension services) or more extensively and systematically on a regular (e.g., semiannual) basis, especially through national campaigns often called Child Health Days, which routinely achieve 80% or greater coverage. Nearly four decades of distributing billions of large-dose VA supplements for prevention, coupled with marked declines in mortality attributed to the intervention, attests to the acceptance, potential effectiveness, and safety of this approach. Gastrointestinal side effects may occur in ~5% of recipient children.

Increasingly, commercial fortification of dietary ingredients is becoming possible in low-income, deficiency-prone countries, and able to offer a quarter to a full day's recommended allowance of VA. Potential food vehicles should be technically fortifiable at planned levels, and consumed within a range that could be both effective in deficient groups while remaining safe for nutritionally adequate or overconsuming segments of a population. VA fortification has been effectively scaled-up using a few products in few countries so far, but will likely rise with opportunity. Successful products have included sugar, nonfat milk powder, wheat flour nonrefrigerated margarine, and vegetable oils. A slow but steadily rising trend in food fortification will likely occur in years ahead as processed foods become more widely consumed and as the food industry becomes engaged in solving VA and other micronutrient deficiency problems.

Biofortification of major staple grains and tubers, such as rice, maize, and sweet potatoes, with beta-carotene have been shown to be potentially effective in improving VA status in poor settings. Dietary diversification is widely held to be the most culturally appropriate and potentially sustainable approach to preventing VA deficiency. Although pilot trials show efficacy of a variety of dietary approaches in improving VA intake and status, data on effectiveness and cost of population food-based interventions remain lacking. Dietary intakes can be improved through home and school gardening initiatives, nutrition education, and social marketing of locally available food sources of VA. However, effective dietary change requires a thorough understanding of local cultural, food system, and behavioral factors that increase the risk of VA deficiency.

Glossary

Retinoic acid The active metabolite of vitamin A in most tissues of the body.

Retinol activity equivalent (RAE) The unit of dietary vitamin A quantification.

Retinol-binding protein The transport protein for vitamin A (retinol) in plasma.

Visual cycle The reactions that recycle retinol and 11-*cis*-retinal in the rods and cones of the retina.

Vitamin A deficiency Clinical manifestations that include low plasma retinol, loss of visual function, alterations to epithelia, and abnormal gene expression.

Vitamin A: Physiology, Dietary Sources, and Requirements

Vitamin A (retinol) is a fat-soluble micronutrient that is required by all vertebrates for vision and the normal functioning of epithelial tissues, the immune system, and reproduction. Vitamin A was discovered in 1913 as an essential growth and survival factor for young rats. The active compound was shown to be a minor lipid present in eggs, butter, whole milk, and fish liver oils. Soon thereafter, vitamin A was characterized chemically as all-*trans*-retinol, a 20-carbon lipid alcohol that is present only in foods of animal origin, often referred to as 'preformed vitamin A.' A second form of vitamin A was isolated from deep-yellow and green leafy vegetables and characterized as β-carotene, a 40-carbon hydrocarbon, referred to as provitamin A. The nutritional requirement for vitamin A can be fully met by a diet containing only preformed retinol (as for carnivores), only provitamin A carotenoids (as for herbivores and humans who consume a strictly vegetarian diet), or a mixture of both as is typical for omnivores. These carotenoids include mainly β-carotene and less amounts of α-carotene and β-cryptoxanthin.

Although retinol or its esters and β-carotene are the nutritional forms of vitamin A provided by diet, both must undergo metabolic reactions to generate the two principal bioactive molecules: 11-*cis*-retinal, required for vision, and retinoic acid, a metabolite that functions as a regulator of gene expression in nearly all tissues. Retinoic acid has important effects on embryogenesis, immune function, reproduction, and the maintenance of healthy cells in essentially all tissues. Adequate dietary vitamin A is therefore thought to be important for the prevention of cancer and degenerative diseases.

Besides the natural forms of vitamin A, a large number of structurally related analogs have been synthesized as potential therapeutic agents. The term 'retinoid' is now used to describe both the natural forms of vitamin A and synthetic analogs, even though the latter typically do not possess all of the biological properties of vitamin A.

Major Molecules in Vitamin A Biochemistry and Physiology

Vitamin A and its metabolites comprise numerous molecules that differ in isomeric form and oxidation state. The major forms are the retinol, its esters, retinal, and retinoic acid. Additional polar metabolites of retinol and retinoic acid are often formed before excretion. The all-*trans* isomer is the most abundant and most stable isomer. In the retina, 11-*cis*-retinal is the functional form, acting as an essential component of rhodopsin (see the Section on Vision).

Retinol is considered the parent molecule of the vitamin A family (**Figure 1**). Its double bonds are typically in the all-*trans* conformation although tissues and plasma may also contain low levels of 9-*cis* and 13-*cis* retinol. In foods and most storage tissues of the body, retinol is esterified with a long-chain fatty acid and stored as retinyl ester. Fatty acid esters of retinol, especially retinyl palmitate, oleate, and stearate, predominate in most tissues.

Additionally, natural variant forms of retinol are present in some foods and human tissues, including vitamin A_2 (3,4 didehydroretinol), which is found in tissues of freshwater fish and produced metabolically in human skin, and α-retinol, an isomer of retinol. These forms have lower vitamin A activity than retinol itself.

Oxidative metabolism is essential for the physiological functions of vitamin A. **Figure 2** illustrates key processes in retinol metabolism. Retinol is oxidized within cells to generate retinal, which is generally a transient metabolite that can either be reduced back to form retinol, allowing for cycling between these two forms, or further oxidized in an irreversible reaction to form retinoic acid. All-*trans*-retinoic acid is the major acidic form of vitamin A with widespread effects on gene expression. 9-*cis*-Retinoic acid has also been proposed to function in gene regulation but its *in vivo* activity remains uncertain. 13-*cis*-Retinoic acid is found naturally, probably as a metabolite, as well as being clinically useful as a prodrug that can be slowly converted to all-*trans*-retinoic acid.

Polar metabolites of retinol or retinoic acid are formed by the addition of hydroxyl or keto groups to the cyclohexenyl ring structure, generally at positions 4 or 18, or by formation of epoxides such as 5,6 epoxy-retinoic acid. Retinol, retinoic acid, and more polar metabolites may be conjugated with glucuronic acid, forming retinyl and retinoyl-β-glucuronide. Conjugation renders these metabolites water soluble and they are found mostly in bile and to some extent in urine, suggesting they are formed as terminal excretion products. Generally, their biological activity is low and their biologic half-life is short.

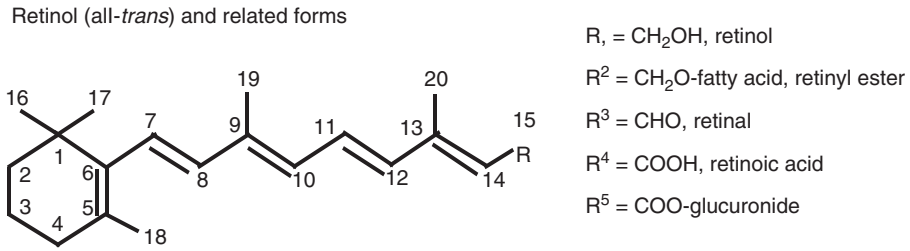

Figure 1 Structure of all-*trans*-retinol and several related forms.

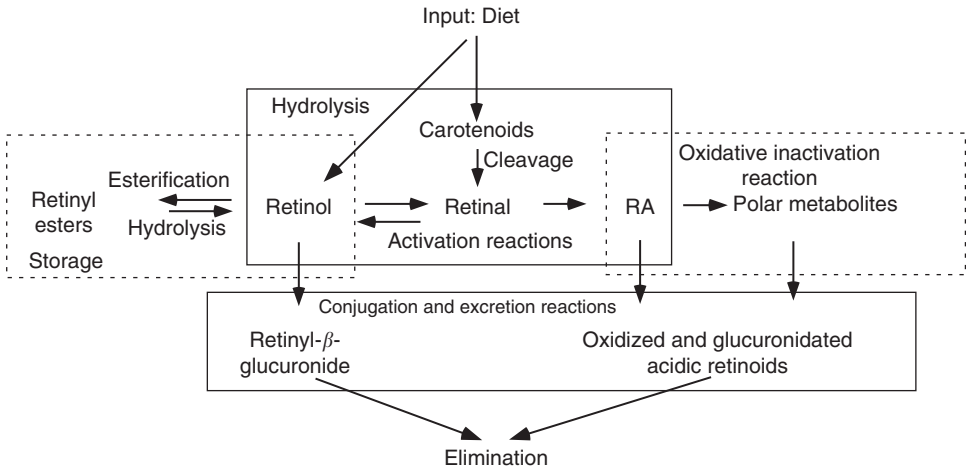

Figure 2 Schematic of principal reactions of vitamin A metabolism.

Transport

The solubility of most retinoids in plasma and cells depends on their association with specific proteins.

Retinol-Binding Protein (RBP4)

Plasma retinol is transported by a specific 21-kDa transport protein, RBP (gene name *RBP4*). Most RBP is synthesized in the liver (see the Section on Hepatic Vitamin A Uptake, Storage, and Release), but some extrahepatic organs also produce it. Each RBP molecule binds a single molecule of all-*trans*-retinol in a noncovalent manner; this complex is referred to as holo-RBP. Holo-RBP associates in plasma with a cotransport protein, transthyretin (TTR), to form a molecular complex of approximately 75 kDa.

Cellular RBPs

Several cellular RBPs are present in the cytoplasm of many types of cells. These proteins, designated CRBP-I, -II, -III, and -IV, and cellular retinoic acid-binding proteins, CRABP-I and -II, are similar in structure and size ($\sim$14.6 kDa). Each contains a single binding site that preferentially binds a particular form of retinoid (retinol, retinal, or retinoic acid), often preferring a specific isomer. Each protein is expressed in different tissue-specific patterns. These proteins function as chaperones that confer aqueous solubility on their lipophilic retinoid and target them to specific enzymes for metabolism.

Nuclear Retinoid Receptors

Two families of nuclear retinoid receptor proteins, retinoic acid receptor (RAR) and retinoid X receptor (RXR), reside mainly in the nucleus where they form dimers capable of binding to specific DNA sequences in retinoid-responsive target genes. The RAR (RARα, β, and γ) and RXR (RXRα, β, and γ) are transcription factors that become activated on binding of ligand, e.g., all-*trans*-retinoic acid for RARs and potentially 9-*cis*-retinoic acid for RXRs. Ligand binding facilitates the recruitment of proteins that modify chromatin and either positively or negatively regulate gene transcription. The RXR also form heterodimers with several other nuclear hormone receptors, namely those for vitamin D, thyroid hormone, certain fatty acids and lipophilic hormones, and xenobiotic agents. Numerous posttranslational protein modifications of the RAR and RXR have been described which further modulate their activity.

Absorption and Metabolism

Intestinal Metabolism

Dietary retinyl esters must be hydrolyzed in the lumen of the small intestine, emulsified, and incorporated into lipid micelles before retinol can be absorbed into the mucosa

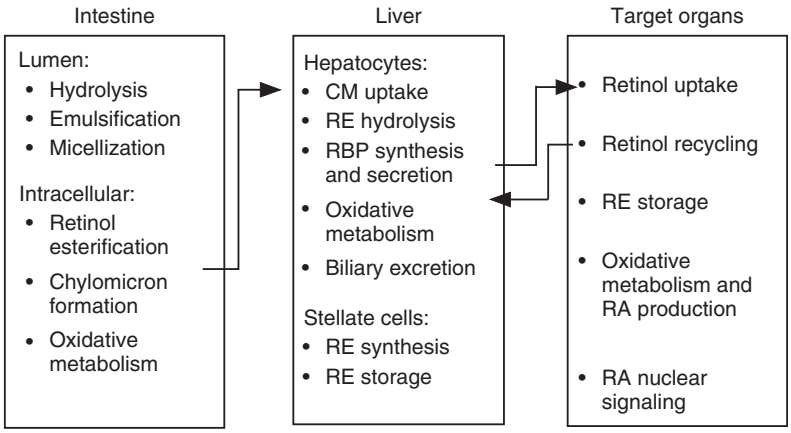

Figure 3 Major physiological processes occurring in the intestine, liver, and target organs. Target organs include eyes, immune system, reproductive organs, and other epithelial tissues including the intestine and liver. CM, chylomicron; RA, retinoic acid; RBP, retinol-binding protein; RE, retinyl ester.

(Figure 3). Several retinyl ester hydrolase (REH) enzymes are present in pancreatic juice or situated on the brush border of duodenal and jejunal enterocytes. For greatest efficiency, these processes require an adequate amount of bile salts and a small quantity of dietary fat, approximately 5%, consumed concomitantly. The retinol molecules then diffuse into the enterocyte where they are bound to CRBP-II and then esterified by the enzyme lecithin:retinol acyltransferase (LRAT). Animals lacking LRAT have been shown to absorb vitamin A poorly, consistent with observations that retinyl ester formation is important for vitamin A absorption. The overall efficiency of intestinal retinol absorption is quite high, approximately 70–90%, and not significantly downregulated when vitamin A consumption increases. Thus, it is possible to absorb too much vitamin A when it is consumed in excess.

β-Carotene is absorbed less efficiently, on the order of 9–22%, than retinol. Provitamin A carotenoids are cleaved in the enterocytes by carotene monooxygenases (BCOs), generating retinal that can be rapidly metabolized to retinol, then esterified. However, humans absorb approximately one-third of ingested β-carotene intact, without cleavage, and this β-carotene is directly incorporated into chylomicrons.

Although most retinol and β-carotene is transformed to retinyl ester in the intestine, a small fraction is oxidized to retinoic acid and then absorbed into the portal vein and systemic circulation. The metabolism of small amounts of dietary 9-*cis*-β-carotene may be a source of 9-*cis*-retinoids in tissues.

Hepatic Vitamin A Uptake, Storage, and Release

After chylomicrons enter lymph and plasma, their triglyceride component is rapidly hydrolyzed, producing smaller chylomicron remnants which still contain newly absorbed vitamin A. Small amounts of the newly absorbed vitamin A, or β-carotene, from chylomicrons and remnants may enter adipose and other tissues including the mammary glands during lactation; however, most chylomicron remnants are cleared rapidly into liver parenchymal cells (hepatocytes) by receptor-mediated endocytosis (Figure 3). The majority of the retinyl ester molecules delivered in this manner undergo rapid hydrolysis, after which retinol is transferred by a process still not well defined into hepatic stellate cells (HSCs) where the retinol is bound to CRBP-I and esterified by LRAT. The HSCs contain predominantly retinyl palmitate and retinyl stearate which, along with other lipids, form numerous small lipid droplets that are characteristic of HSCs. When vitamin A nutrition is adequate, $>90\%$ of the body's total vitamin A resides in HSCs. Extrahepatic tissues also contain small numbers of similar-appearing stellate cells, suggesting the presence of a network of vitamin A-storing cells throughout the body.

Retinyl esters in HSCs can be hydrolyzed, apparently in response to signals that vitamin A is required in other tissues, and the liberated retinol is then transferred back to hepatocytes where it combines with newly synthesized RBP, and is secreted through the Golgi apparatus. Before or shortly after secretion into plasma, holo-RBP binds noncovalently with a tetramer of TTR to form the holo-RBP–TTR transport complex described earlier.

Plasma Concentrations

The concentration of retinol is kept within a nearly constant range, staying close to ~ 2 and 1.7 µmol retinol per liter of plasma in adults, and somewhat lower in children. RBP concentrations are generally somewhat higher and thus RBP is normally 80–90% saturated with retinol. Apo-RBP (i.e., RBP without retinol) displays a reduced affinity for TTR and therefore it is readily filtered in the kidneys, and then catabolized or lost in urine.

In the postprandial period after ingestion of vitamin A, a significant proportion of total plasma retinol is present as retinyl ester. As most blood specimens are collected in the fasting state, these postprandial retinyl esters are usually not measured.

Relationship of Plasma Retinol to Liver Retinol Concentration

The relationship of plasma vitamin A to liver vitamin A concentration has been studied in humans and animals. The steady levels of plasma retinol are generally maintained at a

nearly constant concentration even though liver vitamin A concentrations may vary widely, reflecting close homeostatic regulation. If liver vitamin A reserves fall below a concentration of approximately 20–30 μg retinol per gram liver, then the secretion of holo-RBP from the hepatocytes into plasma is compromised. Under these conditions plasma retinol (holo-RBP) levels fall, until either additional vitamin A is consumed or until nearly all of the vitamin A in liver is used. Clinical signs of vitamin A deficiency begin to manifest themselves when plasma retinol becomes inadequate to support the secretion of holo-RBP and thus to maintain normal functions in peripheral tissues.

As liver and plasma retinol levels fall, RBP synthesis in the liver still continues. If retinol is then administered, it can immediately combine with preexisting apo-RBP and be rapidly secreted into plasma as holo-RBP. A useful test for adequate versus inadequate liver vitamin A stores has been developed based on this finding of rapid secretion of holo-RBP when the liver's vitamin A is insufficient and apo-RBP has built up.

Changes due to Metabolic Disturbances

When the rate of protein synthesis falls, as in states of protein or energy malnutrition, the concentrations of plasma retinol, RBP, and TTR also fall. Plasma RBP and TTR levels are sometimes used as clinical indicators of visceral protein synthesis. During infection or inflammation, the biosynthesis of RBP and TTR is also compromised, even if liver vitamin A reserves may be adequate. Other nutritional and metabolic disturbances can lead to similar decreases in plasma retinol, RBP, and TTR. Thus, laboratory values for plasma retinol must be interpreted cautiously, because not all low levels signal a deficiency of vitamin A.

The consumption of vitamin A over time in amounts that greatly exceed needs, or acute intake of very large doses results in elevated liver vitamin A levels, and potentially in hypervitaminosis A, discussed in the Section on Hypervitaminosis A and Vitamin A Toxicity. This condition is associated with persistent liver levels >300 μg retinol per gram liver. The levels of plasma holo-RBP still remain almost normal, but total vitamin A in plasma increases due to the presence of retinyl esters carried by plasma lipoproteins. Clinically, the presence of retinyl esters in fasting plasma state is a signal of possible hypervitaminosis A.

Vitamin A Kinetics

RBP and TTR each have a relatively short half-life in the circulation, ~ 0.5 and 2–3 days, respectively. Thus the maintenance of relatively stable plasma concentrations necessitates that they be nearly continuously synthesized.

Studies of plasma retinol kinetics have shown that each molecule of retinol circulates through the plasma compartment several times before it is irreversibly degraded (see the Section on Tissue Retinoid Metabolism). In one study of a healthy young man who consumed 105 μmol of retinyl palmitate in a test meal, 50 μmol of retinol passed through his plasma per day, whereas only 4 μmol d^{-1} was degraded. Unlike retinol, the RBP protein does not appear to be recycled, implying that new molecules of RBP must be synthesized for the continued recycling of retinol from the periphery back to the liver. Some extrahepatic tissues, such as kidney and adipose, contain RBP mRNA at levels ~ 5–10% that in liver. The kidney evidently plays a very significant role in the recycling and conservation of retinol after the glomerular filtration of holo-RBP. Holo-RBP can bind to renal epithelial cells and cross the epithelium by transcytosis, which appears to be a mechanism for the recovery of retinol after filtration. Adipose tissue may be another source of plasma RBP. Additionally, adipose-derived RBP has been reported to have adipokine-like activity.

Overall, the body is very efficient at conserving retinol, but relatively inefficient in degrading and eliminating retinoids when vitamin A is consumed in amounts that substantially exceed requirements. Intakes in excess of physiological needs thus result in a build up of retinyl esters in tissues, especially in, but not limited to, the liver.

Tissue Retinoid Metabolism

Recently, a novel protein has been discovered which serves as a receptor for holo-RBP in certain tissues. The protein, known as Stra6, is located on the plasma membrane of certain cells or organs, including the retinal pigment epithelium (RPE), lungs, and other tissues. However, the liver does not appear to express Stra6, yet studies have shown that retinol recycles from plasma to liver, suggesting the existence of other uptake mechanisms as well.

Although the majority of the body's vitamin A is stored in the liver, many organs contain small depots of retinyl esters, which are thought to be critical for the generation of bioactive retinoids formed by oxidative metabolism (see **Figure 2**). Several enzymes of the alcohol dehydrogenase, the short-chain dehydrogenase/reductase, and aldehyde dehydrogenase gene families may participate in these oxidative reactions. However, most of these enzymes are also capable of oxidizing other substrates and therefore elucidating the specific oxidative metabolism of retinoids has been difficult.

Retinoic acid is generally present in tissues at nanomolar concentrations, far lower than that of retinol. The half-life of retinoic acid is very short, a few hours or less, implying that it must be generated almost continuously to maintain appropriate cellular concentrations. Some tissues, such as brain, derive most of their retinoic acid through metabolism whereas other tissues such as liver obtain retinoic acid mostly by uptake from plasma.

Both retinol and retinoic acid can be oxidized on their ring structure, usually at carbon 4, to yield hydroxy and oxo metabolites. The oxidative metabolism of retinoic acid is in part autoregulated because elevated concentrations of retinoic acid induce the expression of cytochrome P450 enzymes, especially CYP26A1, a retinoic acid 4-hydroxylase that is capable of converting retinoic acid to polar metabolites. Ring-oxidized metabolites of retinol and retinoic acid are normally present at low concentrations in plasma, probably because they are readily removed by the liver and conjugated with glucuronic acid and readily excreted. Although tissue retinoid levels are normally maintained within a narrow range by a balance of production and oxidation, it is possible for homeostatic mechanisms to be overwhelmed when vitamin A or retinoids

are taken in excess (see the Section on Hypervitaminosis A and Retinoid Toxicity).

Physiological Actions

Vision

The RPE constitutes a layer of epithelial cells underlying the photoreceptors that take up retinol bound to RBP from choroid capillaries and convert it into retinyl esters for storage and ultimately to be used for the generation of 11-*cis*-retinal. As per requirement, 11-*cis*-retinal is transported by interstitial RBP (IRBP) to the adjacent layer of rod and cone photoreceptor cells where 11-*cis*-retinal combines covalently with the protein opsin in rods to generate the visual pigment rhodopsin, and, similarly, with proteins known as iodopsins in cones to form red-, green-, and blue-sensitive pigments. 11-*cis*-Retinal is very efficient in absorbing light. Although retinal in organic solvent absorbs maximally in the ultraviolet range at ~365 nm, the absorption maximum is shifted into the visible range by the combination of 11-*cis*-retinal with opsin. The rod cell outer segment is densely packed with membrane disks that, overall, contain some 10^8 molecules of rhodopsin per cell. Nevertheless, the small quantity of vitamin A present in the retina would be inadequate to maintain vision if it were not for the presence of the visual cycle, which constitutes a recycling process in which 11-*cis*-retinal is regenerated after it has been photobleached by light. Some of these recycling reactions take place in the rods and cones and others in the RPE. The regeneration of 11-*cis*-retinal, referred to as dark adaptation, is relatively slow (on the order of minutes) as compared with the very rapid process of photoisomerization. However, vision normally continues without a period of blindness as long as retinol can be drawn from the retinyl ester storage pool in the RPE, rapidly isomerized to 11-*cis*-retinol, reoxidized to 11-*cis*-retinal, and passed by IRBP to the rod cells where rhodopsin can be regenerated. When the RPE's supply of retinyl esters is low, as occurs during the development of vitamin A deficiency, the visual cycle slows significantly. The clinical outcome is night blindness, a loss of the ability to quickly adapt to darkness again after exposure to bright light. Night blindness is an early indicator of incipient vitamin A deficiency.

The cornea is an avascular tissue, however holo-RBP is present in the lacrimal glands and tears, and this vitamin A is likely to provide the substrate for the local formation of retinoic acid, which then maintains corneal cell integrity. Retinoid deficiency results in a loss of goblet cells (mucin-secreting cells). The presence of corneal xerosis and Bitôt's spots (foamy deposits of cells and bacteria, usually at the outer quadrants of the eye) is an indicator of severe vitamin A deficiency. Persons with these symptoms need vitamin A immediately to prevent corneal ulceration, which results in lifelong blindness.

Functions in Cell Differentiation

Epithelial tissues (the skin, respiratory tract, immune system, reproductive organs, etc.) are especially sensitive to a lack of vitamin A, and often to an excess of retinoids as well. The systemic effects of vitamin A deficiency include dryness of the skin (follicular hyperkerotosis), loss of goblet cells in the trachea and respiratory tract, and a generalized flattening of epithelia (squamous metaplasia, sometimes with keratinization). The hematopoietic system is also affected, as are reproductive organs. In the testes, spermatogenesis is inhibited by vitamin A deficiency.

Although either a lack or an excess of retinoids is known to affect many organ systems, the developing embryo and the immune system have been studied most intensively. During development, retinoids are required from the early, postgastrulation stage of development. Retinoic acid has been proposed to be an essential morphogen whose concentration is a key determinant of the expression of several developmentally important genes, particularly *Hox* genes that are critical for the formation of the body pattern. Some *Hox* genes contain a retinoic acid-response element (RARE) and thus can respond directly to retinoic acid. Both deficiency and excess of vitamin A, as well as excess of retinoid analogs, can cause severe developmental defects.

For the immune system, studies in vitamin A-deficient animal models have demonstrated many abnormal immune responses, including reduced T-cell counts and an altered pattern of T-cell subsets. The functions of cytotoxic cells, such as cytotoxic T cells, natural killer cells, and macrophages, are often low. Similarly, it is often the case that the production of cytokines that regulate T-cell immunity and antibody production by B cells is also low, or dysregulated, in vitamin A deficiency. The migration of T and B cells to sites of immune stimulation may also be impaired by vitamin A deficiency.

In children at risk of vitamin A deficiency, vitamin A either given prophylactically or as therapy during illness has resulted in a significant reduction in mortality and in the severity of diseases such as measles.

Dietary Sources and Nutritional Equivalency

Preformed vitamin A is present at highest concentration in liver and fish oils; it is present at lower concentrations in nonorgan meats and eggs (**Table 1**). Vitamin A, usually as retinyl palmitate for improved stability, is also used in food fortification and supplement preparation. In the USA, approximately two-thirds of vitamin A is consumed preformed and the rest is consumed as carotenoids, but the proportions vary widely depending on dietary patterns.

Units of Nutritional Activity

Because vitamin A exists in multiple forms and the efficiency of utilization of some of its forms, including carotenoids, is lower than that of preformed vitamin A, it is necessary to express 'the total bioactivity of vitamin A' in terms of equivalents. The currently accepted nutritional equivalents, established in 2001 by the Institute of Medicine (IOM), are expressed in retinol activity equivalents (RAE), where 1 μg RAE corresponds to the activity of 1 μg of all-*trans*-retinol or 2 μg of β-carotene in oily solution. It is now considered that, on

average, carotenoids must be ingested in the following amounts to provide the equivalent nutritional value of 1 μg of all-*trans*-retinol (1 RAE):

1. Two micrograms of supplemental β-carotene (in an oily, easily absorbed solution).
2. Twelve micrograms of β-carotene, or 24 μg of α-carotene or β-cryptoxanthin in fruits and vegetables (due to association of carotenoids with the food matrices, and therefore reduced digestibility).

Food labels still use the older international unit (IU), which is outdated by the above-mentioned considerations. One IU equals 0.3 μg of all-*trans*-retinol. Another indicator of nutritional value used in food labeling is the percentage daily value (%DV). This is a less quantitative but convenient means to compare foods for their nutritional value, and is used in Table 1 to compare differences among vitamin A-containing foods.

Table 1 Food sources of vitamin A

Food	*%DV*
Animal sources of preformed vitamin A	
Liver, beef, cooked, 3 oz	545
Liver, chicken, cooked, 3 oz	245
Fat-free milk, fortified with vitamin A, 1 cup	10
Chedder cheese, 1 oz	6
Milk, whole, 3.25% fat, 1 cup	5
Plant sources of β-carotene and other provitamin A carotenoids	
Carrots, boiled, 1/2 cup slices	270
Carrot, 1 raw ($7\frac{1}{2}$-in long)	175
Cantaloupe, raw, 1 cup	110
Spinach, raw, 1 cup	55
Apricot nectar, canned, 1/2 cup	35
Papaya, raw, 1 cup cubes	30
Tomato juice, canned, 6 oz	15
Peach, raw, 1 medium	6

%DV = Daily Value. DVs are reference numbers based on the recommended dietary allowance (RDA). They were developed to help consumers determine if a food contains a lot or a little of a specific nutrient. The DV for vitamin A is 5000 IU (1500 μg retinol). Most food labels do not list a food's vitamin A content. The percent DV (%DV) listed on the table above indicates the percentage of the DV provided in one serving. Percent DVs are based on a 2000-calorie diet.
Source: http://ods.od.nih.gov/factsheets/VitaminA-HealthProfessional/#en18 (last accessed May 20 2011).

Recommended Dietary Allowances (RDAs) and Tolerable Upper Intake Levels for Vitamin A

RDAs for the USA and Canada were updated by the IOM in 2001. Guidelines were also established for a tolerable upper intake level (UL). The 2001 RDA and UL for vitamin A for various life stages are listed in Table 2. The UL is defined as the highest intake of a nutrient that is likely to pose no risk of adverse health effects in nearly all healthy individuals. For vitamin A, the UL applies specifically to 'preformed vitamin A' (e.g., retinol, but not carotenoids) from foods, fortified foods, and supplements combined. For several life stage groups, the UL is less than three times the RDA (Table 2). The UL was based on epidemiological studies showing teratogenic effects of excessive vitamin A taken during pregnancy, and on minimizing the risk of liver damage due to hypervitaminosis A. For children, the RDA and UL values were scaled down based on body weight. The recommendations of the Food and Agricultural Organization/World Health Organization (FAO/WHO) tend to be slightly lower than the RDAs defined by the IOM.

Hypervitaminosis A and Vitamin A Toxicity

Hypervitaminosis A is a rare but serious and sometimes fatal condition. It can arise acutely after consumption of very large amounts of preformed vitamin A, or slowly after the persistent intake of lesser, but still excessive, amounts of preformed vitamin A. Most cases have resulted from excessive use of vitamin A-containing supplements, whereas similar symptoms have been reported in some patients taking prescription retinoids for therapy. The clinical signs of vitamin A toxicity include nausea and vomiting, headache, dizziness, blurred vision, lack of muscular

Table 2 Recommended dietary allowances (RDAs) for vitamin A in micrograms (μg), retinol activity equivalents (RAE), and international units (IUs), and tolerable upper intake levels (UL, μg retinol per day) for childen and adults

Age (years)	*Children*	*Men*	*Women*	*Pregnancy*	*Lactation*
RDA (μg RAE per day)					
1–3	300 μg or 1000 IU				
4–8	400 μg or 1333 IU				
9–13	600 μg or 2000 IU				
14–18	900 μg or 3000 IU	700 μg or 2330 IU	750 μg or 2500 IU	1200 μg or 4000 IU	
≥19	900 μg or 3000 IU	700 μg or 2330 IU	770 μg or 2565 IU	1300 μg or 4335 IU	
UL (μg retinol per day)					
1–3	600 μg				
4–8	900 μg				
9–13	1700 μg				
14–18		3000 μg	2800 μg	2800 μg	2800 μg
≥19		3000 μg	3000 μg	3000 μg	3000 μg

Source: http://ods.od.nih.gov/factsheets/VitaminA-HealthProfessional/ (last accessed 24 December 2010).

coordination, abnormal liver function, and pain in weight-bearing bones and joints.

There is little that can be done to treat vitamin A toxicity besides eliminating the intake of vitamin A or use of retinoids, and there is no antidote. For prevention, care should be exercised to avoid overconsumption of preformed vitamin A including in supplements (see ULs, **Table 2**).

Individuals who consume large amounts of carotenoid-rich foods or juices may develop yellowing of the skin (carotenodermia), especially in fatty tissues and the palms of the hands. This condition is considered benign and the yellow color will gradually subside after intake of carotene is reduced to a normal level.

VITAMIN B_6

Physiology

DA Bender, University College London, UK

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Acrodynia In rats, a specific dermatitis associated with vitamin B_6 deficiency, leading to scaly paws and ears. Formerly used as the basis for a biological assay of vitamin B_6.
Ataxia Inability to coordinate voluntary muscle movement as a result of neurological damage.
Decarboxylation The removal of carbon dioxide form an amino acid to yield an amine.
Glycogen phosphorylase The enzyme that catalyses the stepwise removal of glucose units (as glucose 1-phosphate) from the storage carbohydrate glycogen in liver and muscle.
Hyperhomocysteinemia An elevated blood concentration of homocysteine, a risk factor for cardiovascular disease.
Myelin The lipid sheath around nerve fibers.
Neuropathy Damage to nerves.
Racemization The reaction in which the D- and L-isomers of an amino acid are interconverted.
Schiff base The product of condensation between an amino group and an aldehyde or ketone.
Transamination The reaction in which the amino group of an amino acid is transferred onto an oxo-acid (keto-acid), yielding the corresponding amino acid, and forming the oxo-acid carbon skeleton of the donor amino acid

Dietary Forms, Biological Availability, and Metabolism

The main form of vitamin B_6 in foods is pyridoxal phosphate, bound to enzymes. There is also a small amount of pyridoxamine phosphate. In plant foods, a significant amount of the vitamin is present as pyridoxine.

A number of plants contain relatively large amounts of pyridoxine glycosides, which are only approximately 50% biologically available. Approximately 15% of the total vitamin B_6 in typical diets is present as glycosides, some of which is hydrolyzed by intestinal mucosal glycosidases. Some can be absorbed intact, and may be a substrate for tissue glycosidases, or may be excreted into the urine unchanged. The overall dietary vitamin B_6 is approximately 75% biologically available.

A proportion of the vitamin B_6 in foods may be biologically unavailable, especially after heating, as a result of the formation of (phospho)pyridoxyllysine by reduction of the aldimine (Schiff base) by which pyridoxal phosphate is bound to the ε-amino groups of lysine residues in proteins. Although some of this pyridoxyllysine may be useable, because it is a substrate for pyridoxine phosphate oxidase, it is also a vitamin B_6 antimetabolite, and, even at relatively low concentrations, can accelerate the development of deficiency in experimental animals maintained on deficient diets. In the 1950s, there was an outbreak of vitamin B_6 deficiency among infants fed on formula that had been overheated in manufacture, resulting in the formation of relatively large amounts of pyridoxyllysine.

Digestion and Absorption

Pyridoxal phosphate bound as a Schiff base to lysine in dietary proteins is released on digestion of the protein. The phosphorylated vitamers are dephosphorylated by membrane-bound alkaline phosphatase in the intestinal mucosa; pyridoxal, pyridoxamine, and pyridoxine are all absorbed rapidly by passive diffusion and even very high doses are well absorbed. Intestinal mucosal cells have pyridoxine kinase and pyridoxine phosphate oxidase so that there is net accumulation by metabolic trapping. Much of the ingested pyridoxine is released into the portal circulation as pyridoxal, after dephosphorylation at the serosal surface.

Metabolism and Transport

Much of the absorbed vitamin is taken up by the liver, although other tissues can also take up the unphosphorylated vitamers from the circulation. Uptake is by carrier-mediated diffusion, followed by metabolic trapping as phosphate esters. Pyridoxine and pyridoxamine phosphates are oxidized to pyridoxal phosphate. All tissues have pyridoxine kinase activity, but pyridoxine phosphate oxidase is found only in the liver, kidney, and brain (**Figure 1**).

Pyridoxine phosphate oxidase is a flavoprotein, and its activity declines markedly in riboflavin deficiency. Despite this central role of riboflavin in vitamin B_6 metabolism, blood and tissue concentrations of pyridoxal phosphate are not affected by riboflavin deficiency, and riboflavin nutrition appears to have little effect on vitamin B_6 nutritional status.

 http://dx.doi.org/10.1016/B978-0-12-375083-9.00275-0

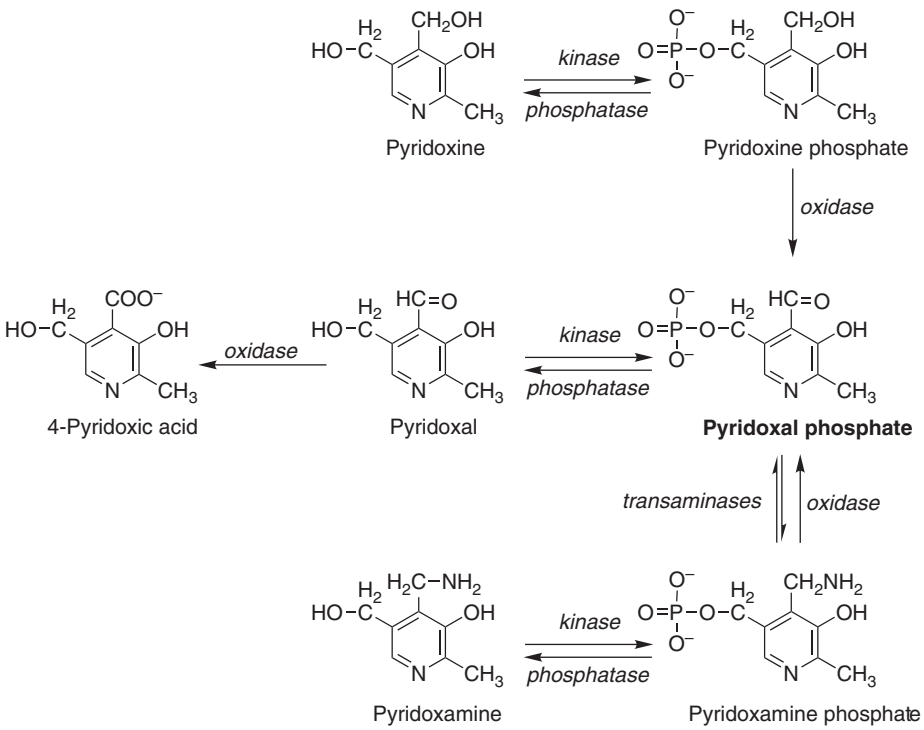

Figure 1 Metabolism of vitamin B_6.

Pyridoxine phosphate oxidase is inhibited by its product, pyridoxal phosphate. This is not simple product inhibition, but involves binding at a specific inhibitor site on the enzyme. The normal intracellular concentration of free pyridoxal phosphate causes significant inhibition, which indicates that this is a physiologically important mechanism in the control of tissue pyridoxal phosphate.

Pyridoxine is rapidly phosphorylated in the liver and other tissues. Pyridoxal phosphate does not cross cell membranes, and uptake and efflux of the vitamin in most tissues is as pyridoxal. Pyridoxal phosphate is exported from the liver bound to albumin. Much of the free pyridoxal phosphate in the liver is hydrolyzed to pyridoxal, which is also exported, and circulates bound both to albumin and to hemoglobin in erythrocytes. Free pyridoxal remaining in the liver is rapidly oxidized to 4-pyridoxic acid, which is the main excretory product of the vitamin.

Extrahepatic tissues take up pyridoxal from the plasma. Pyridoxal phosphate is hydrolyzed to pyridoxal, which can cross cell membranes, by extracellular alkaline phosphatase, and then trapped intracellularly by phosphorylation.

Tissue concentrations of pyridoxal phosphate are controlled by the balance between phosphorylation and dephosphorylation. The activity of phosphatases acting on pyridoxal phosphate is greater than that of the kinase in most tissues. This means that pyridoxal phosphate that is not bound to enzymes will be dephosphorylated and hence will leave the cell by diffusion. Thus, there is little accumulation of pyridoxal phosphate in tissues, other than that which is bound to enzymes and other proteins (e.g., hormone receptors).

Free pyridoxal either leaves the cell or is oxidized to 4-pyridoxic acid by aldehyde dehydrogenase, which is present in all tissues, and also by hepatic and renal aldehyde oxidase. 4-Pyridoxic acid is the main excretory product of vitamin B_6, and its excretion reflects recent intake more than the state of underlying tissue reserves of the vitamin. Small amounts of pyridoxal and pyridoxamine are also excreted in the urine, although much of the active vitamin B_6 that is filtered at the glomerulus is reabsorbed in the kidney tubules. High doses of pyridoxine are largely excreted unchanged.

Storage and Body Reserves

There is no specific storage of vitamin B_6 in the body; as discussed in the Section on Metabolism and Transport, pyridoxal phosphate that is not bound to enzymes is rapidly dephosphorylated, oxidized to 4-pyridoxic acid, and excreted.

The total body pool of vitamin B_6 is of the order of 1000 μmol (167 mg), 15 μmol kg^{-1} bodyweight. Approximately 80% of this is in muscle, associated with glycogen phosphorylase. This does not seem to function as a true reserve of the vitamin and is not released from muscle in times of deficiency, nor does it turn over as rapidly as pools in other tissues.

Muscle pyridoxal phosphate is released into the circulation (as pyridoxal) in starvation, as muscle glycogen reserves are exhausted, and there is less requirement for glycogen phosphorylase activity. Under these conditions, it is available for redistribution to other tissues, especially the liver and kidney,

to meet the increased requirement for transamination of amino acids for gluconeogenesis.

Metabolic Functions of Vitamin B_6

The metabolically active vitamer is pyridoxal phosphate, which is involved in many reactions of amino acid metabolism, where the carbonyl group is the reactive moiety, in glycogen phosphorylase, where it is the phosphate group that is important in catalysis, and in the release of hormone receptors from tight nuclear binding, where again it is the carbonyl group that is important.

The Role of Pyridoxal Phosphate in Amino Acid Metabolism

The various reactions of pyridoxal phosphate in amino acid metabolism (**Figure 2**) all depend on the same chemical principle: the ability to stabilize amino acid carbanions and hence to weaken bonds around the α-carbon of the substrate. This is achieved by the reaction of the α-amino group with the carbonyl group of the coenzyme to form a Schiff base (aldimine).

Pyridoxal phosphate is bound to enzymes, in the absence of the substrate, by the formation of an internal Schiff base to the ε-amino group of a lysine residue at the active site. Thus, the first reaction between the substrate and the coenzyme is transfer of the aldimine linkage from this ε-amino group to the α-amino group of the substrate.

The ring nitrogen of pyridoxal phosphate exerts a strong electron-withdrawing effect on the aldimine, and this leads to weakening of all three bonds around the α-carbon of the substrate. In nonenzymic model systems, all the possible pyridoxal-catalyzed reactions are observed: α-decarboxylation, aminotransfer, racemization, and relevant side-chain elimination and replacement reactions. By contrast, enzymes generally show specificity for the reaction pathway followed; which bond is cleaved will depend on the orientation of the Schiff base relative to reactive groups of the catalytic site. However, a number of decarboxylases and enzymes that catalyze side-chain elimination reactions of amino acids undergo gradual inactivation as a result of catalyzing the half-reaction of transamination, leaving (catalytically inactive) pyridoxamine phosphate at the catalytic site.

α-Decarboxylation

If the electron-withdrawing effect of the ring nitrogen is primarily centered on the α-carbon–carboxyl bond, the result is decarboxylation of the amino acid with the release of carbon dioxide. The resultant carbanion is then protonated, and the primary amine corresponding to the amino acid is displaced

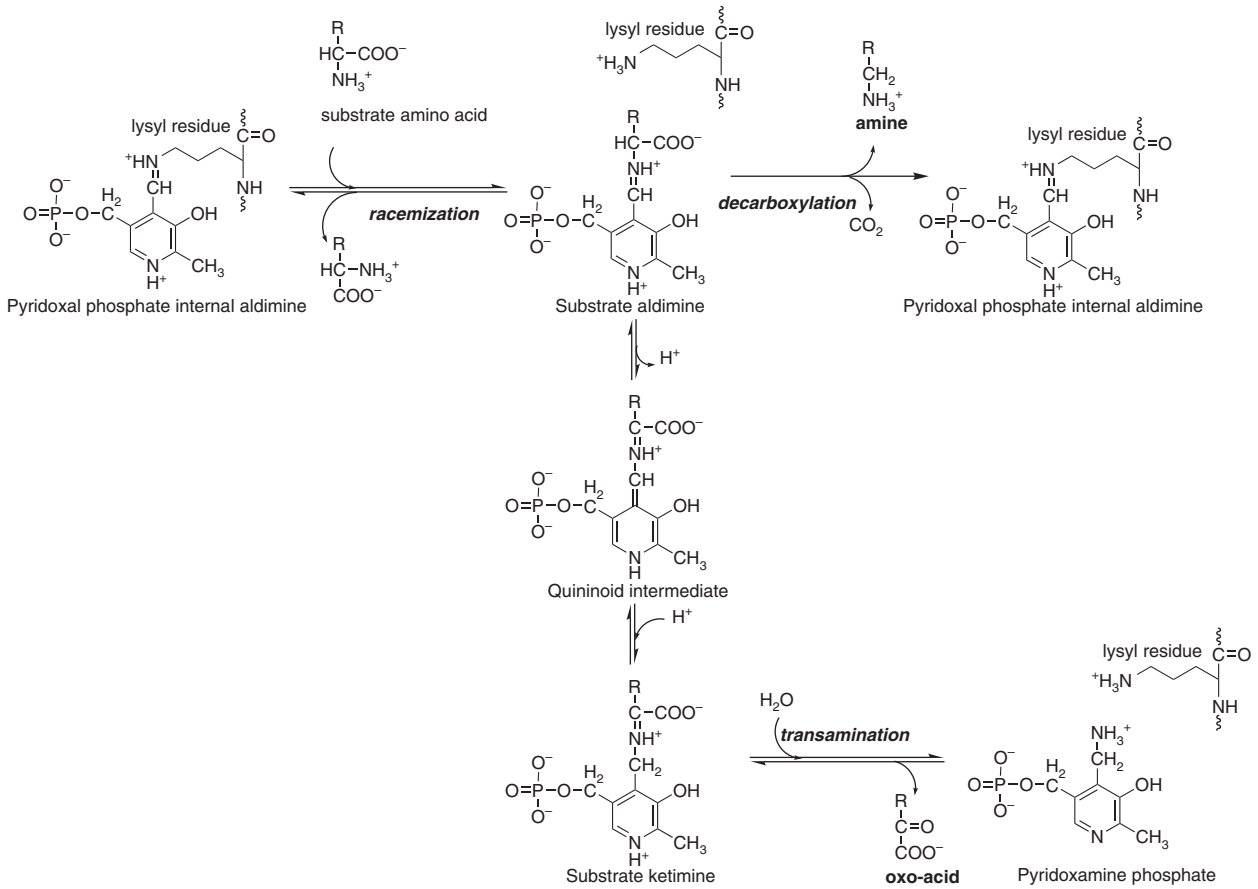

Figure 2 Roles of vitamin B_6 in amino acid metabolism.

by the lysine residue at the active site, with reformation of the internal Schiff base.

A number of the products of the decarboxylation of amino acids are important as neurotransmitters and hormones (5-hydroxytryptamine, the catecholamines dopamine, noradrenaline and adrenaline; histamine, and γ-aminobutyrate (GABA)) and as the diamines and polyamines involved in the regulation of DNA metabolism.

Racemization of Amino Acids

Deprotonation of the α-carbon of the amino acid leads to tautomerization of the Schiff base to yield a quinonoid ketimine. The simplest reaction that the ketimine can undergo is reprotonation at the now symmetrical α-carbon. Displacement of the substrate by the reactive lysine residue results in the racemic mixture of D- and L-amino acid.

Amino acid racemases have long been known to be important in bacterial metabolism, because several D-amino acids are required for the synthesis of cell wall mucopolysaccharides. D-Aspartate and D-serine are mammalian neurotransmitters, D-aspartate plays a role in signaling during brain development, and there are racemases in the hypothalamus and other brain regions.

Transamination

Hydrolysis of the α-carbon–amino bond of the ketimine formed by deprotonation of the α-carbon of the amino acid results in the release of the 2-oxo-acid corresponding to the amino acid substrate, and leaves pyridoxamine phosphate at the catalytic site of the enzyme. In this case, the internal Schiff base to the reactive lysine residue is not reformed. This is the half-reaction of transamination. The process is completed by the reaction of pyridoxamine phosphate with a second oxo-acid substrate, forming an intermediate ketimine, followed by the reverse of the reaction sequence shown in **Figure 2**, releasing the amino acid corresponding to this second substrate after displacement from the aldimine by the reactive lysine residue to reform the internal Schiff base.

Transamination (**Figure 3**) is of central importance in amino acid metabolism, providing pathways for the catabolism of all of the amino acids, except lysine, which does not undergo transamination. Many of these reactions are linked to the amination of 2-oxoglutarate to glutamate or glyoxylate to glycine, which are substrates for oxidative deamination, reforming the oxo-acids. Transamination reactions also provide a pathway for the synthesis of those amino acids, for which there is an alternative source of the oxo-acid (the nonessential amino acids). Indeed, the nonessential amino acids can be defined as those whose oxo-acids can be formed other than from the amino acid itself.

Side-Chain Elimination and Replacement Reactions

The third bond in the Schiff base aldimine that can be labilized by the electron-withdrawing effect of the ring nitrogen of pyridoxal phosphate is that between the α-carbon and the side chain of the amino acids, resulting in a variety of $\alpha - \beta$ elimination and $\beta - \gamma$ replacement reactions.

The Role of Pyridoxal Phosphate in Glycogen Phosphorylase

Glycogen phosphorylase catalyzes the sequential phosphorolysis of glycogen to release glucose-1-phosphate; it is thus the key enzyme in the utilization of muscle and liver reserves of glycogen.

Unlike other pyridoxal phosphate-dependent enzymes, in which the carbonyl group is essential for catalysis, the internal Schiff base between pyridoxal phosphate and lysine in glycogen phosphorylase is not broken during the reaction. The catalytic region of the coenzyme is the 5′-phosphate group. The initial stage in the phosphorolysis of glycogen is protonation of the glycosidic oxygen of the polysaccharide by inorganic phosphate. The resultant oxycarbonium ion is stabilized by the inorganic phosphate. The role played by pyridoxal phosphate is that of a proton shuttle or buffer to stabilize the oxycarbonium–phosphate ion pair, allowing covalent binding of the phosphate to the oxycarbonium ion, to form glucose-1-phosphate.

The Role of Pyridoxal Phosphate in Steroid Hormone Action

Pyridoxal phosphate plays a role in modulating the action of those hormones that act by binding to a nuclear receptor

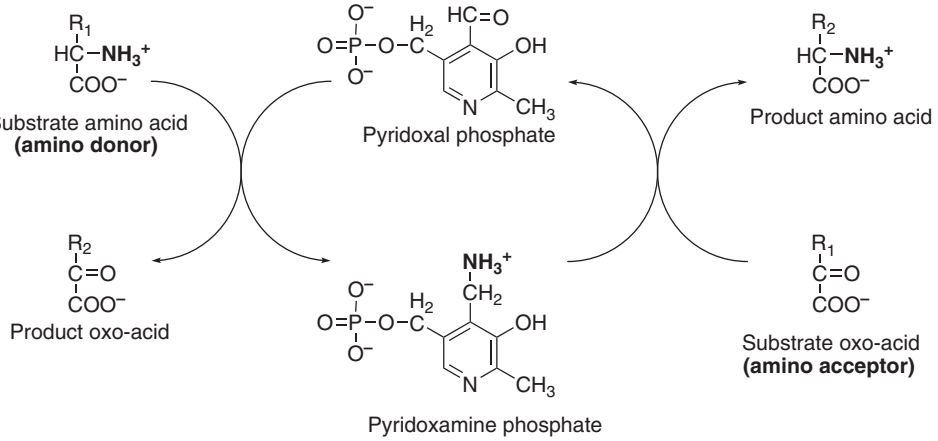

Figure 3 The role of vitamin B_6 in transamination reactions.

protein, inducing transcription of DNA, and hence regulating gene expression and protein synthesis. Such hormones include androgens, estrogens, progesterone, glucocorticoids, calcitriol (the active metabolite of vitamin D), retinoic acid and other retinoids, and thyroid hormone. Target-tissue specificity of hormone action is ensured by the presence of receptor proteins with a zinc finger motif, which are responsible for both nuclear uptake of the hormone and the interaction with DNA and nucleoproteins to initiate gene expression.

Pyridoxal phosphate reacts with a lysine residue in the receptor protein, and displaces the hormone–receptor complex from tight nuclear binding. *In vitro*, reaction with pyridoxal phosphate also inhibits the binding of receptor protein to isolated DNA and chromatin. The effect is specific for the phosphorylated vitamer, suggesting that there is a specific pyridoxal-phosphate-binding site on the receptor protein, and it occurs at low concentrations of pyridoxal phosphate, of the same order of magnitude as in tissues under normal conditions.

This suggests that pyridoxal phosphate acts as a cofactor in the release of hormone–receptor complexes from tight nuclear binding, resulting in the release of the receptor from the nucleus, termination of hormone action, and recycling receptor protein for further uptake of hormone.

In experimental animals, vitamin B_6 deficiency results in increased and prolonged nuclear uptake and retention of steroid hormones in target tissues, and there is enhanced sensitivity to hormone action. Deficient animals show greater induction of uterine peroxidase, and considerably greater suppression of the hypothalamic secretion of luteinizing hormone, by estrogens than do vitamin B_6-supplemented controls. In vitamin B_6-deficient male animals, there is an increased mitotic response of the prostate to low doses of testosterone. Deficient male animals have a higher activity of ornithine decarboxylase (an androgen-induced enzyme) in the liver and deficient females have higher renal ornithine transaminase (an estrogen-induced enzyme). The induction of hepatic tyrosine transaminase and tryptophan dioxygenase by glucocorticoids is also enhanced in vitamin B_6-deficient animals.

In a variety of cells in culture that have been transfected with a glucocorticoid, estrogen, or progesterone response element linked to a reporter gene, acute vitamin B_6 depletion (by incubation with 4-deoxypyridoxine) leads to a two-fold increase in the expression of the reporter gene in response to hormone action. Conversely, incubation of these cells with high concentrations of pyridoxal, leading to a high intracellular concentration of pyridoxal phosphate, results in a halving of the expression of the reporter gene in response to hormone stimulation.

Criteria of Adequacy and Assessment of Nutritional Status

Plasma Concentrations of the Vitamin

The fasting plasma concentration of either total vitamin B_6 or, more specifically, pyridoxal phosphate, is widely used as an index of vitamin B_6 nutritional status. The generally accepted criteria of adequacy are shown in **Table 1**.

Table 1 Indices of vitamin B_6 nutritional status

	Adequate status
Plasma total vitamin B_6	>40 nmol (10 μg) l^{-1}
Plasma pyridoxal phosphate	>30 nmol (7.5 μg) l^{-1}
Erythrocyte alanine aminotransferase activation coefficient	<1.25
Erythrocyte aspartate aminotransferase activation coefficient	<1.80
Erythrocyte aspartate aminotransferase	>0.13 units (8.4 μkat) l^{-1}
Urine 4-pyridoxic acid	>3.0 μmol per 24 h >1.3 mmol per mol creatinine
Urine total vitamin B_6	>0.5 μmol per 24 h >0.2 mmol per mol creatinine
Urine xanthurenic acid after a 2-g tryptophan load	<65 μmol per 24 h increase
Urine cystathionine after a 3-g methionine load	<350 μmol per 24 h increase

Conditions that involve increased plasma activity of alkaline phosphatase may result in reduced plasma pyridoxal phosphate, without affecting the tissue concentrations of pyridoxal phosphate or vitamin B_6 nutritional status as assessed by other criteria. There is a compensatory increase in the circulating concentration of pyridoxal, which is the main form of tissue uptake. Despite the decline in plasma pyridoxal phosphate in pregnancy, which has been widely interpreted as indicating vitamin B_6 depletion, the plasma concentration of (pyridoxal phosphate plus pyridoxal) is unchanged. This suggests that determination of plasma pyridoxal phosphate alone may not be a reliable index of vitamin B_6 nutritional status.

Urinary Excretion of 4-Pyridoxic Acid

Approximately half of the normal dietary intake of vitamin B_6 is excreted as 4-pyridoxic acid. Urinary excretion of 4-pyridoxic acid will largely reflect recent intake of the vitamin rather than underlying nutritional status; the criteria for the assessment of 4-pyridoxic acid excretion are shown in **Table 1**.

Coenzyme Saturation of Transaminases

Various pyridoxal phosphate-dependent enzymes compete with each other for the available pool of coenzyme. Thus, the extent to which an enzyme is saturated with its coenzyme provides a means of assessing the adequacy of the body pool of coenzyme. This can be determined by measuring the activity of the enzyme before and after the activation of any apoenzyme present in the sample by incubation with pyridoxal phosphate added *in vitro*. Both erythrocyte aspartate and alanine transaminases are commonly used; the results are expressed as either the percentage stimulation of activity by added pyridoxal phosphate or the activation coefficient – the

ratio of activity with added coenzyme to that without added coenzyme.

It seems to be normal for a proportion of pyridoxal phosphate-dependent enzymes to be present as an inactive apoenzyme, without a coenzyme. This may be a mechanism for metabolic regulation. It is possible that increasing the intake of vitamin B_6, so as to ensure complete saturation of pyridoxal phosphate-dependent enzymes, may not be desirable.

Metabolic Loading Tests

A direct test of the adequacy of an individual's intake to meet his or her idiosyncratic metabolic requirement is the ability to metabolize a test dose of a substrate whose metabolism is dependent on the vitamin. For vitamin B_6, two metabolic loading tests can be used, although neither can be considered to be reliable for population studies of vitamin B_6 status.

The Tryptophan Load Test

The oxidative pathway of tryptophan metabolism is shown in Figure 4. Kynureninase is a pyridoxal phosphate-dependent enzyme, and in vitamin B_6 deficiency, its activity is lower than that of tryptophan dioxygenase. This means that there is a considerable accumulation of both hydroxykynurenine and kynurenine, sufficient to allow greater than usual metabolic flux through kynurenine transaminase, resulting in increased formation of kynurenic and xanthurenic acids. Although kynurenine transaminase is also pyridoxal phosphate dependent, it is relatively unaffected in vitamin B_6 deficiency. Kynureninase is very sensitive to vitamin B_6 deficiency because it undergoes a slow inactivation as a result of catalyzing the half-reaction of transamination in addition to its normal reaction. The resultant enzyme with pyridoxamine phosphate at the catalytic site is catalytically inactive and can only be reactivated if there is an adequate concentration of pyridoxal phosphate to displace the pyridoxamine phosphate.

Xanthurenic and kynurenic acids are easy to measure in urine, so that the ability to metabolize a test dose of 2 g or 5 g of tryptophan has been widely adopted as a convenient and sensitive index of vitamin B_6 nutritional status. However, induction of tryptophan dioxygenase by glucocorticoid hormones will result in a greater rate of formation of kynurenine and hydroxykynurenine than the capacity of kynureninase, and will thus lead to increased formation of kynurenic and xanthurenic acids – an effect similar to that seen in vitamin B_6 deficiency. Such results may be erroneously interpreted as indicating vitamin B_6 deficiency in a variety of subjects whose

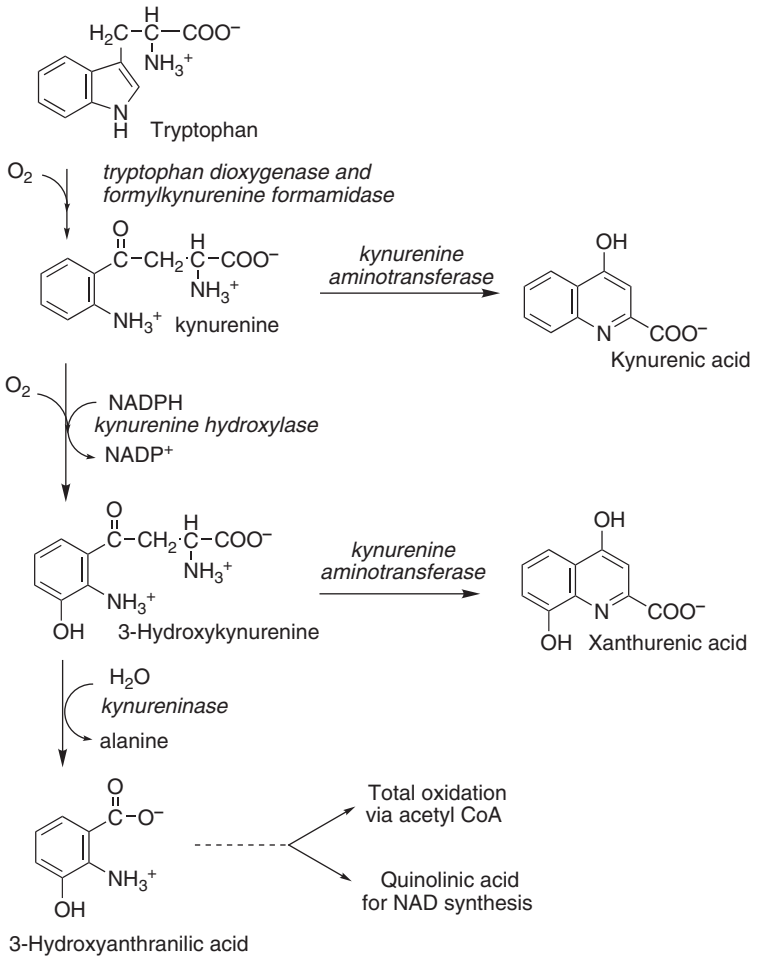

Figure 4 The oxidative pathway of tryptophan metabolism – the basis of the tryptophan load test for vitamin B_6 status.

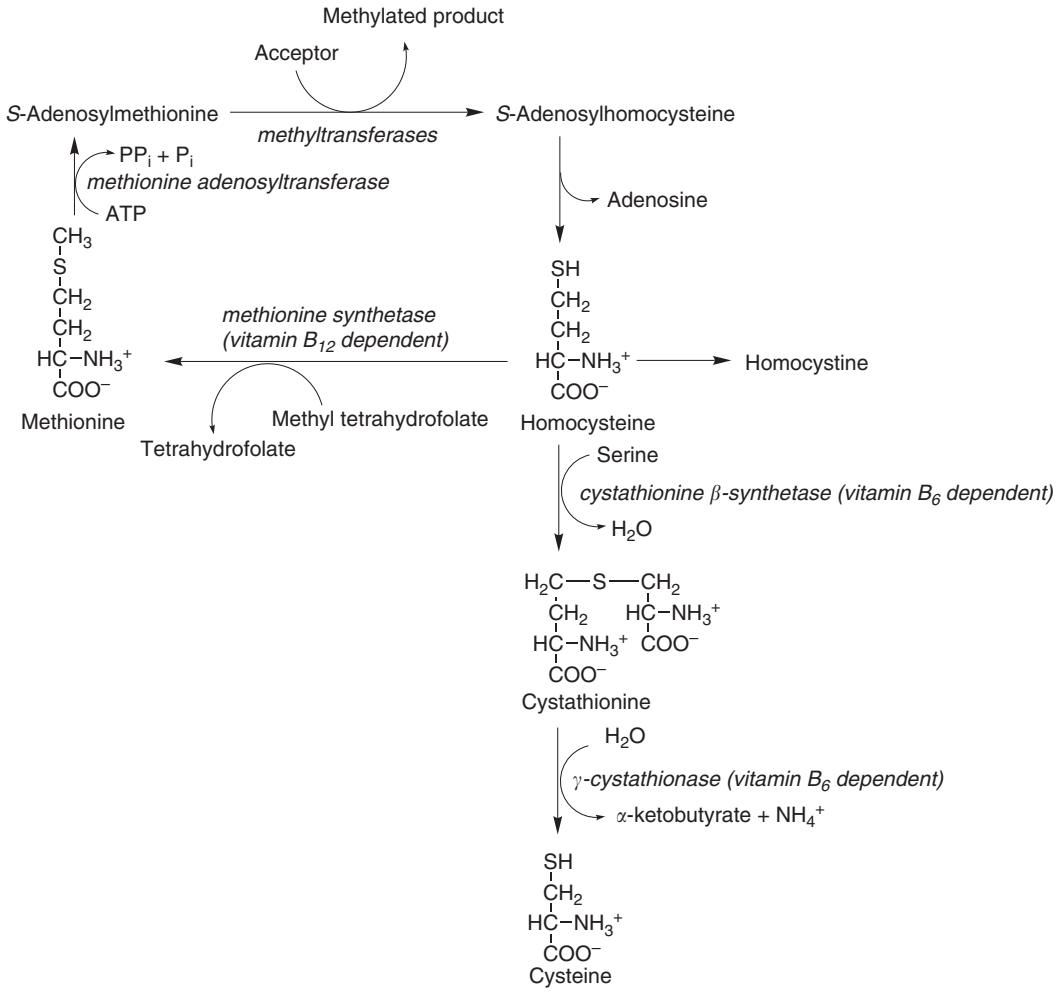

Figure 5 The pathway of methionine metabolism – the basis of the methionine load test for vitamin B_6 status.

problem is increased glucocorticoid secretion as a result of stress or illness, not vitamin B_6 deficiency.

Inhibition of kynureninase, for example, by estrogen metabolites, also results in the accumulation of kynurenine and hydroxykynurenine and hence increased formation of kynurenic and xanthurenic acids, again yielding results that falsely suggest vitamin B_6 deficiency. This has been widely, but incorrectly, interpreted as estrogen-induced vitamin B_6 deficiency – it is in fact simple competitive inhibition by estrogen metabolites of the enzyme that is the basis of the tryptophan load test.

There is normally a considerable excess of either apokynureninase or kynureninase that has undergone transamination and has pyridoxamine phosphate at the catalytic site, in the liver. This can be activated by (relatively high concentrations of) pyridoxal phosphate. The abnormalities of tryptophan metabolism associated with increased activity of tryptophan dioxygenase, or inhibition of kynureninase by estrogen metabolites, are thus corrected by the administration of high doses of vitamin B_6, although they are not in fact due to deficiency.

This means that although the tryptophan load test may be an appropriate index of status in controlled depletion/repletion studies to determine vitamin B_6 requirements, it is not an appropriate index of status in population studies.

The Methionine Loading Test

The metabolism of methionine, shown in **Figure 5**, includes two pyridoxal phosphate-dependent steps, catalyzed by cystathionine synthetase and cystathionase. In vitamin B_6 deficiency, there is an increase in the plasma concentration of homocysteine, and increased urinary excretion of cystathionine and homocysteine, both after a loading dose of methionine and under basal conditions. The ability to metabolize a test dose of methionine therefore provides an index of vitamin B_6 nutritional status. Because measurement of homocysteine and cystathionine is technically less easy than measurement of xanthurenic and kynurenic acids, the methionine load test has been less widely used than the tryptophan load test.

Approximately 10–25% of the population has a genetic predisposition to hyperhomocysteinemia, which is a risk

factor for atherosclerosis and coronary heart disease, as a result of polymorphism in the gene for methylenetetrahydrofolate reductase. As discussed below, there is little evidence that supplements of vitamin B_6 reduce fasting plasma homocysteine in these subjects, and like the tryptophan load test, the methionine load test may be an appropriate index of status in controlled depletion/repletion studies to determine vitamin B_6 requirements, but not in population studies.

Requirements and Recommendations

The total body pool of vitamin B_6 is of the order of 15 μmol (3.7 mg) kg^{-1} of bodyweight. Isotope tracer studies suggest that there is a turnover of approximately 0.13% per day, and hence a minimum requirement for replacement of 0.02 μmol (5 μg) kg^{-1} of bodyweight, approximately 350 μg day^{-1} for a 70-kg adult.

Most studies of vitamin B_6 requirements have followed the development of abnormalities of tryptophan (and sometimes also methionine) metabolism during depletion and normalization during repletion with graded intakes of the vitamin. Although the tryptophan and methionine loading tests are unreliable as indices of vitamin B_6 nutritional status in field studies, under the controlled conditions of depletion/repletion studies, they do indeed provide a useful indication of the state of vitamin B_6 nutrition.

Although approximately 80% of the total body pool of vitamin B_6 is associated with muscle glycogen phosphorylase, this pool turns over relatively slowly. The major metabolic role of the remaining 20% of total body vitamin B_6, which turns over considerably more rapidly, is in amino acid metabolism. Therefore, *a priori*, it seems likely that protein intake will affect vitamin B_6 requirements.

Individuals maintained on (experimental) vitamin B_6-deficient diets develop abnormalities of tryptophan and methionine metabolism faster, and their blood vitamin B_6 declines more rapidly, when their protein intake is high. Similarly, during repletion of deficient subjects, tryptophan and methionine metabolism and blood vitamin B_6 are normalized faster at low than at high levels of protein intake.

Depletion/repletion studies suggest a mean requirement of 13 μg of vitamin B_6 per gram of dietary protein; the UK Reference Nutrient Intake (RNI) and the EU Population Reference Intake (PRI) are based on 14–16 μg g^{-1} of protein. At average intakes of approximately 100 g of protein per day, this yields an RNI or a PRI of 1.4–1.6 mg of vitamin B_6.

The relevance of the studies involving low and high protein intakes to normal nutrition is unclear – they were conducted using extremes of protein intake: 40 g day^{-1} for the low protein intake, which is barely adequate to maintain nitrogen balance, and 150 g day^{-1} for the high intake, which is considerably higher than the average intakes of protein. The correlation of plasma pyridoxal phosphate with intake of pyridoxine in depletion/repletion studies is the same as that with pyridoxine per gram dietary protein, suggesting that protein intake within the normal range is not relevant to determining vitamin B_6 requirements. On this basis, the US Estimated Average Requirement (EAR) is 1.1 mg day^{-1} and the Recommended Daily Amount (RDA) is 1.3 mg.

Possible Benefits of Higher Levels of Intake

The identification of hyperhomocysteinemia as an independent risk factor in atherosclerosis and coronary heart disease has led to suggestions that higher intakes of vitamin B_6 than are currently considered adequate to meet requirements may be desirable. As shown in **Figure 5**, homocysteine is intermediate in methionine metabolism, and may have one of two metabolic fates: remethylation to methionine (a reaction that is dependent on vitamin B_{12} and folic acid) or onward metabolism leading to the synthesis of cysteine (the vitamin B_6-dependent trans-sulfuration pathway).

Among elderly survivors of the Framingham study cohort (aged 67–96), hyperhomocysteinemia was most significantly correlated with low folate status, but there was also a significant association with low vitamin B_6 status. However, a number of studies have shown that while folate supplements lower fasting homocysteine in moderately hyperhomocysteinemic subjects, 10 mg day^{-1} vitamin B_6 has little additional effect.

Vitamin B_6 supplements do, however, reduce the peak plasma concentration of homocysteine following a test dose of methionine. This can probably be explained by the kinetics of the enzymes involved. The K_m of cystathionine synthetase is 10-fold higher than that of methionine synthetase. Under basal conditions, little homocysteine is metabolized by way of the trans-sulfuration pathway. It is only after a loading dose of methionine, when homocysteine increases to relatively high levels, that the activity of cystathionine synthetase, rather than the availability of its substrate, is limiting for trans-sulfuration.

It is thus unlikely that intakes of vitamin B_6 above amounts that are adequate to prevent metabolic signs of deficiency will be beneficial in lowering plasma concentrations of homocysteine, and in any case, most intervention studies of vitamin supplementation to lower plasma homocysteine have shown no effect on death from myocardial infarction, although some have shown a reduction in the incidence of stroke.

Vitamin B_6 Requirements of Infants

Estimation of the RDA for vitamin B_6 of infants presents a problem, and there is a clear need for further research to achieve a realistic estimate of infants' requirements. Human milk, which must be assumed to be adequate for infant nutrition, provides only approximately 40–100 μg l^{-1} or 3–8 μg of vitamin B_6 per gram of protein – very much lower than the apparent requirement for adults. There is no reason why infants should have a lower requirement than adults, and indeed because they must increase their total body pool of the vitamin as they grow, they might be expected to have a proportionally higher requirement than adults.

A first approximation of the vitamin B_6 needs of infants emerged from studies of those who convulsed as a result of gross deficiency caused by overheated infant milk formula in the 1950s. At intakes of 60 μg day^{-1}, there was an incidence of convulsions of 0.3%. Provision of 260 μg day^{-1} prevented or cured convulsions, but 300 μg day^{-1} was required to normalize tryptophan metabolism. This is almost certainly a considerable overestimate of requirements, because pyridoxyllysine,

formed by heating the vitamin with proteins, has antivitamin activity, and would therefore result in a higher apparent requirement.

Based on the body content of 15 μmol (3.7 mg) of vitamin B_6 kg^{-1} of bodyweight, and the rate of weight gain, the minimum requirement for infants over the first 6 months of life would appear to be 100 μg (417 nmol) day^{-1} to establish tissue reserves.

Pharmacological Uses and Toxicity of Vitamin B_6 Supplements

Supplements of vitamin B_6 ranging from 25 to 500 mg day^{-1}, and sometimes higher, have been recommended for the treatment of a variety of conditions in which there is an underlying physiological or biochemical mechanism to justify the use of supplements, although in most cases, there is little evidence of efficacy. Such conditions include postnatal depression, depression, and other side effects associated with oral contraceptives, hyperemesis of pregnancy, and the premenstrual syndrome.

Supplements have also been used empirically, with little or no rational basis, and little or no evidence of efficacy, in the treatment of a variety of conditions, including acute alcohol intoxication, atopic dermatitis, autism, dental caries, diabetic neuropathy, Down's syndrome, Huntington's chorea, schizophrenia, and steroid-dependent asthma. There is some evidence that vitamin B_6 supplements in pregnancy reduce the incidence of dental caries.

Doses of 100 mg day^{-1} have been reported to be beneficial in the treatment of the carpal tunnel syndrome or what has been called tenosynovitis. Although some studies suggest that there is some beneficial effect, two systematic reviews show that vitamin B_6 is no more effective than placebo.

Vitamin B_6 has been reported to be effective in suppression of lactation, although other reports have shown no difference from placebo. Because the vitamin suppresses the increase in prolactin induced by treatment with the dopamine receptor antagonist pimozide, and because lactation is also suppressed by the dopamine agonist bromocriptine, it has been suggested that it acts to stimulate dopaminergic activity in the hypothalamus. However, it is more likely that its action is by reduction in target-tissue responsiveness to the steroid hormones that stimulate prolactin secretion.

Doses of 50–200 mg day^{-1} have an antiemetic effect, and the vitamin is widely used, alone or in conjunction with other antiemetics, to minimize the nausea associated with radiotherapy and to treat pregnancy sickness. There is no evidence that vitamin B_6 has any beneficial effect in pregnancy sickness, nor those women who suffer from morning sickness have lower vitamin B_6 nutritional status than other pregnant women. There have been reports of a teratogenic effect of vitamin B_6 used to treat morning sickness, but all of these involved the use of the vitamin together with the sedative Debendox, and there is no evidence that vitamin B_6 itself is teratogenic. However, because it downregulates responsiveness to steroid hormones and retinoids, it is possible that high levels of vitamin B_6 intake may affect embryonic or fetal development.

Vitamin B_6 and the Side Effects of Oral Contraceptives

Although estrogens do not cause vitamin B_6 deficiency, the administration of vitamin B_6 supplements has beneficial effects on some of the side effects of both administered and endogenous estrogens. The supplements act in two main areas: in normalizing glucose tolerance and as an antidepressant.

Impairment of glucose tolerance is common in pregnancy and might indeed be severe enough to be classified as gestational diabetes, which generally resolves at parturition, although in some subjects it may persist, pregnancy having been the trigger for the development of maturity-onset diabetes. High-estrogen oral contraceptives may also cause impaired glucose tolerance. This seems to be the result of increased tissue and blood concentrations of xanthurenic acid, because of the inhibition of kynureninase by estrogen metabolites. Xanthurenic acid forms a complex with insulin, which has little or no hormonal activity. Vitamin B_6 supplements may have a beneficial effect on glucose tolerance by activating apokynureninase or kynureninase that has been inactivated by undergoing transamination.

One of the relatively common side effects of high-estrogen oral contraceptives is depression, affecting approximately 6% of women in some studies. This frequently responds well to the administration of relatively large amounts of vitamin B_6 (generally more than 40 mg day^{-1}). Postnatal depression also responds to similar supplements in some studies.

Again, this does not seem to be due to correction of vitamin B_6 deficiency, but rather to a direct effect of pyridoxal phosphate on the metabolism of tryptophan. High concentrations of pyridoxal phosphate attenuate the response to glucocorticoid hormones; tryptophan dioxygenase is a glucocorticoid-induced enzyme, and thus its synthesis and activity will be reduced by high intakes of vitamin B_6. This reduces the oxidative metabolism of tryptophan and increases the amount available for the synthesis of 5-hydroxytryptamine in the brain. Increased brain 5-hydroxytryptamine synthesis has a mood-elevating effect.

Vitamin B_6 in the Premenstrual Syndrome

The studies showing a beneficial action of vitamin B_6 in overcoming depression associated with oral contraceptives have led to the use of the vitamin in depression and other pathology associated with endogenous estrogens, in the premenstrual syndrome. There is no evidence of poorer vitamin B_6 nutritional status in women who suffer from premenstrual syndrome.

There are few well-controlled studies of the effects of vitamin B_6 in premenstrual syndrome. In general, those who have been properly controlled report little benefit from doses between 50 and 200 mg day^{-1} compared with placebo, although some studies do claim a beneficial effect. Interestingly, meta-analysis of controlled cross-over trials shows that whichever treatment is used second, active vitamin or placebo, is (marginally) more effective. There is no obvious explanation for this observation.

Despite the lack of evidence of efficacy, vitamin B_6 is widely prescribed (and self-prescribed) for the treatment of premenstrual syndrome.

Toxicity of Vitamin B_6

Animal studies have demonstrated the development of signs of peripheral neuropathy, with ataxia, muscle weakness, and loss of balance in dogs given 200 mg pyridoxine HCl per kg of bodyweight for 4075 days, and the development of a swaying gait and ataxia within 9 days at a dose of 300 mg kg^{-1} of bodyweight. At a dose of 50 mg kg^{-1} of bodyweight, there are no clinical signs of toxicity; but histologically, there is a loss of myelin in the dorsal nerve roots. At higher doses, there is more widespread neuronal damage, with loss of myelin and degeneration of sensory fibers in peripheral nerves, the dorsal columns of the spinal cord, and the descending spinal tract of the trigeminal nerve. The clinical signs of vitamin B_6 toxicity in animals regress after withdrawal of these massive doses, but sensory nerve conduction velocity, which decreases during the development of the neuropathy, does not recover fully. The mechanism of the neurotoxic action of vitamin B_6 is unknown.

The development of sensory neuropathy has been reported in patients taking 2–7 g of pyridoxine HCl per day. Although there was residual damage in some patients, withdrawal of these extremely high doses resulted in a considerable recovery of sensory nerve function. Other reports have suggested that intakes as low as 50 mg day^{-1} are associated with neurological damage, although these have been based on patients reporting symptoms rather than on detailed neurological examination.

Based on studies including detailed neurological examination that show no adverse effects of intakes up to 200 mg day^{-1}, the US Institute of Medicine has set a tolerable upper level of intake of pyridoxine from supplements of 100 mg day^{-1}. The UK Food Standards Agency adopted a more cautious approach and, by extrapolation from animal studies, set a safe upper level for daily consumption over a lifetime of 10 mg day^{-1}, while noting that there is no evidence of adverse effects at doses up to 200 mg day^{-1}.

Vitamin B_6 Deficiency

Gross clinical deficiency of vitamin B_6 is more or less unknown. The vitamin is widely distributed in foods, and intestinal flora synthesize relatively large amounts, at least some of which is believed to be absorbed and hence available.

In vitamin B_6-deficient experimental animals, there are more or less specific skin lesions (e.g., acrodynia in the rat) and fissures or ulceration at the corners of the mouth and over the tongue, as well as a number of endocrine abnormalities, defects in the metabolism of tryptophan, methionine and other amino acids, hypochromic microcytic anemia (the first step of heme biosynthesis is a pyridoxal phosphate-dependent reaction), changes in leukocyte count and activity, a tendency of epileptiform convulsions, and peripheral nervous system damage resulting in ataxia and sensory neuropathy. Classical clinical signs of human vitamin B_6 deficiency (which was almost certainly multivitamin deficiency) include sebhorreic dermatitis, depression, and confusion as well as hypochromic microcytic anemia. In controlled studies of vitamin B_6 depletion, electroencephalogram abnormalities develop after a few days and resolve on repletion with the vitamin.

There was an outbreak of vitamin B_6 deficiency in the early 1950s among infants who had been fed a milk formula that had undergone severe heating in manufacture. The probable result of this was the formation of pyridoxyllysine by reaction between pyridoxal phosphate and the ε-amino groups of lysine in proteins. In addition to a number of metabolic abnormalities, many of the affected infants convulsed. They responded to the administration of vitamin B_6 supplements.

Investigation of the neurochemical basis of the convulsions in vitamin B_6 deficiency helped to elucidate the role of γ-aminobutyrate (GABA) as a neurotransmitter; GABA is synthesized by the decarboxylation of glutamate. More recent studies have suggested that the accumulation of hydroxykynurenine in the brain may be the critical factor precipitating convulsions in deficiency; GABA is depleted in the brains of deficient adult and neonate animals, whereas hydroxykynurenine accumulation is considerably more marked in neonates than in adults – only neonates convulse when having vitamin B_6 deficiency. GABA depletion may be a necessary but not a sufficient condition for convulsions when having vitamin B_6 deficiency.

Vitamin B_6 Dependency Syndromes

A small number of cases have been reported of patients with genetic defects that result in an abnormally high requirement for vitamin B_6 in order to maintain the activity of the affected enzyme (**Table 2**). Such vitamin B_6 dependency syndromes have been reported in cases of xanthurenic aciduria, homocystinuria, hypochromic sideroblastic anemia, ornithinemia, and infantile convulsions. The molecular basis of the defects appears to be a severely impaired affinity of the affected enzyme for its cofactor, and patients respond well to doses of 500–1000 mg of vitamin B_6 per day. Apart from the affected enzyme, other biochemical indices of vitamin B_6 nutritional status are normal in these patients. Interestingly, there are very few reports of peripheral neuropathy among such patients treated with high doses of vitamin B_6 for many years.

Groups at Risk of Deficiency

A number of studies have shown that between 10% and 20% of the apparently healthy population have low plasma concentrations of pyridoxal phosphate or an abnormal

Table 2 Vitamin B_6-responsive inborn errors of metabolism

	Enzyme affected
Convulsions of the newborn	Unknown
Cystathioninuria	Cystathionase (see **Figure 5**)
Gyrate atrophy with ornithinuria	Ornithine-δ-aminotransferase
Homocystinuria	Cystathionine synthase (see **Figure 5**)
Primary hyperoxaluria, type I	Peroxisomal alanine–glyoxylate transaminase
Sideroblastic anemia	δ-Aminolevulinate synthase ($\downarrow$ heme synthesis)
Xanthurenic aciduria	Kynureninase (see **Figure 4**)

erythrocyte transaminase activation coefficient, suggesting vitamin B_6 inadequacy or deficiency. In most studies, only one of these indices of vitamin B_6 nutritional status has been assessed. Where both indices have been assessed, although each shows approximately 10% of the population apparently inadequately provided with vitamin B_6, few of the subjects show inadequacy by both criteria. Approximately 10–25% of the US population has an intake of vitamin B_6 that is below the EAR, rising to almost 50% of pregnant women.

There is a decrease in the plasma concentration of vitamin B_6 with increasing age, and some studies have shown a high prevalence of abnormal transaminase activation coefficients in elderly subjects, suggesting that the elderly may be at risk of vitamin B_6 deficiency. It is not known whether this reflects an inadequate intake, a greater requirement, or changes in the tissue distribution and metabolism of the vitamin with increasing age, but the (US) EAR and RDA are higher for individuals over the age of 50.

Drug-Induced Vitamin B_6 Deficiency

A number of drugs that react with carbonyl compounds are capable of causing vitamin B_6 deficiency on prolonged use. These include the antituberculosis drug isoniazid (iso-nicotinic acid hydrazide), penicillamine, and the anti-parkinsonian drugs, benserazide and carbidopa. In general, the main effect is impairment of tryptophan metabolism by inhibition of kynureninase, and hence the development of the niacin deficiency disease, pellagra. The condition therefore responds to the administration of either vitamin B_6 or niacin. Isoniazid also causes peripheral neuropathy, which responds to vitamin B_6 supplements, but not to niacin.

Estrogens and Vitamin B_6 Nutritional Status

There have been many reports of abnormal tryptophan metabolism in women taking estrogens as oral contraceptives and menopausal hormone replacement therapy. These have been widely interpreted as evidence of estrogen-induced vitamin B_6 deficiency. However, this is the result of inhibition of kynureninase by estrogen metabolites, not estrogen-induced deficiency of the vitamin. Where other indices of vitamin B_6 status have been reported, they have been generally unaffected by contraceptive use, again suggesting an effect on tryptophan metabolism *per se*, rather than on vitamin B_6 nutritional status.

In many cases, the metabolism of tryptophan has been normalized by the administration of vitamin B_6 supplements of the order of 20–50 mg day^{-1}, compared with an RDA of 1.4–1.6 mg day^{-1}. It was noted earlier that there is an apparent excess of apokynureninase in the liver and therefore the administration of vitamin B_6 supplements will increase kynurenine metabolism even when there is no preexisting deficiency.

Glossary

Cobalamins Compounds that are collectively known as vitamin B_{12} and contain cobalt in a corrin ring. The cobalt can be attached to one of several sidegroups, including cyanide. Cyanocobalamin is the stable form of the vitamin manufactured for use as supplements and a food fortificant.

Macrocytosis When red blood cells (erythrocytes) are larger than normal.

Transcobalamins Carrier proteins which bind and transport vitamin B_{12}.

Introduction

The cobalamins are a group of closely related and interconvertible compounds with a complex structure that are collectively known by the common name of vitamin B_{12}. Recommended biochemical nomenclature restricts the term 'vitamin B_{12}' for the particular form of cobalamin known as cyanocobalamin. All cobalamins belong to the broader family of corrinoids, which share the characteristic of consisting of a planar four-membered pyrrole ring (corrin ring) containing a central cobalt atom. Cobalamins are distinguished from other corrinoids by possessing both alpha (lower) and beta (upper) axial ligands that are attached to the central cobalt atom (**Figure 1**). The lower ligand consists of a base (5,6-dimethylbenzimidazole) attached to a sugar (ribose), which in turn is attached to a phosphate and an amino-propyl group that ultimately is tethered back to the corrin ring. In the naturally occurring cobalamins the upper ligand is variably a cyano-, hydroxo-, aquo-, methyl-, or adenosylgroup, giving rise to the correspondingly named chemical forms of the vitamin.

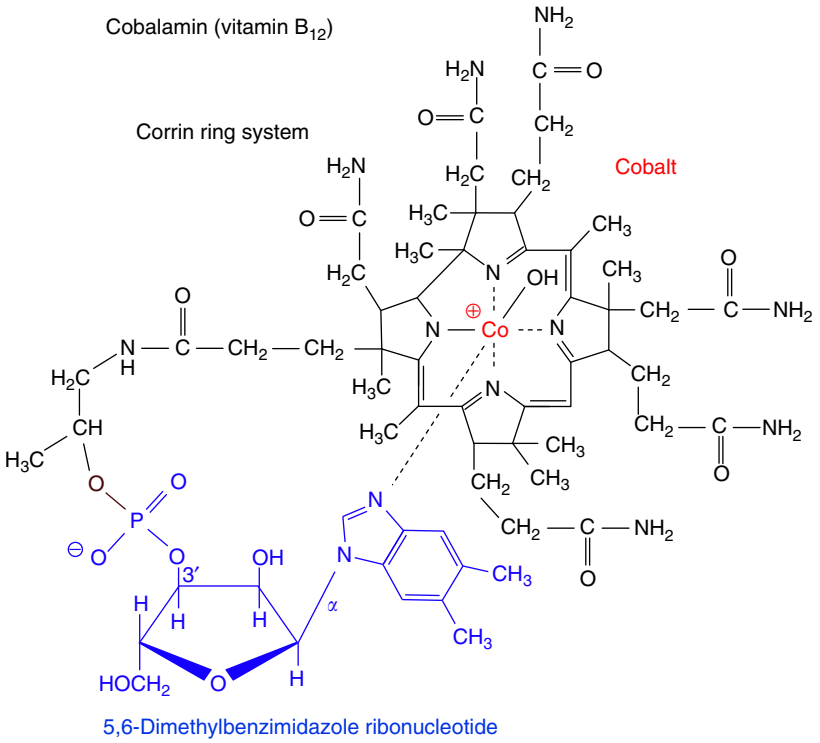

Figure 1 Chemical structure of Cobalamin.

Of these, methylcobalamin and deoxyadenosylcobalamin are the forms that function as coenzymes for metabolic reactions. These are highly sensitive to destruction by light. Cyanocobalamin is a stable form and is therefore used in therapeutic preparations. Hydroxo or aquocobalamin are intermediates during the synthesis of the coenzyme forms. Other forms including sulphito-, nitrito-, and glutathionyl derivatives of cobalamin have also been described, but their precise role in metabolism is not known.

Biochemistry and Metabolic Functions

Only two reactions in humans and other animals are known to require cobalamin (**Figure 2**). One, isomerization of methylmalonyl CoA, which requires deoxyadenosylcobalamin, catalyzed by the enzyme methylmalonyl CoA mutase and is mitochondrial. The other reaction is the transmethylation of homocysteine by 5-methyl-tetrahydrofolate to methionine, catalyzed by the enzyme methionine synthase (N^5-methyl homocysteine methyl transferase), which requires methylcobalamin as coenzyme and is located in the cytosol. It is through their essential roles in this important metabolic reaction that cobalamin and folate interact and are linked with respect to their importance in nutrition. In addition, there are major similarities in the effects of their deficiencies in humans. These will be discussed below. Considering this 'metabolic crossroad' for the two vitamins, it may be pointed out that without adequate supplies of both nutrients, the synthesis of methionine and its derivative *S*-adenosylmethionine (SAM) is disrupted, with consequent profound effects on normal cellular function. Methionine is a key and essential amino acid and normal supply depends critically on recycling through the remethylation pathway (**Figure 3**). Moreover, SAM is the universal methyl donor, essential for more than 100 transmethylation reactions involving amino acid, nucleotide, neurotransmitter, and phospholipid metabolism as well as detoxification reactions.

Apart from methionine the other product of the methionine synthase reaction, which is almost completely irreversible, is tetrahydrofolate (THF). This constitutes the first step by which folate enters bone marrow and other cells from plasma, for its conversion into the various intracellular forms of reduced folate containing a series of one-carbon substituents (**Figure 3**). The active forms of these folate congeners are all polyglutamated by an enzyme, folate polyglutamate synthetase, which cannot use methyl-THF as substrate. THF is the obligate substrate for polyglutamate addition. Consequently, when the methionine synthase reaction is blocked as a result of cobalamin deficiency, there is 'THF starvation'. Methyl-THF accumulates in the plasma, although intracellular folate concentrations fall due to failure of formation of the critical intracellular folate polyglutamates because of 'methyl-folate trapping.' This theory explains the abnormalities of folate metabolism, which occur in cobalamin deficiency (high concentrations of serum folate, low red blood cell folate), and also why the anemia that occurs in cobalamin deficiency will temporarily or partially respond to folic acid in large doses. The explanation of why the serum cobalamin falls in folate deficiency may also be related to impairment of the methionine synthase reaction resulting from reduced formation of methylcobalamin, the predominant circulating form of cobalamin in plasma.

Physiology

The recommended dietary allowance (RDA) for cobalamin in adults, proposed by the Food and Nutrition Board of the Institute of Medicine in 1997, is 2–4 μg. Cobalamins do not occur in plants and are synthesized by certain bacteria, fungi, and algae, which constitute the ultimate source of all

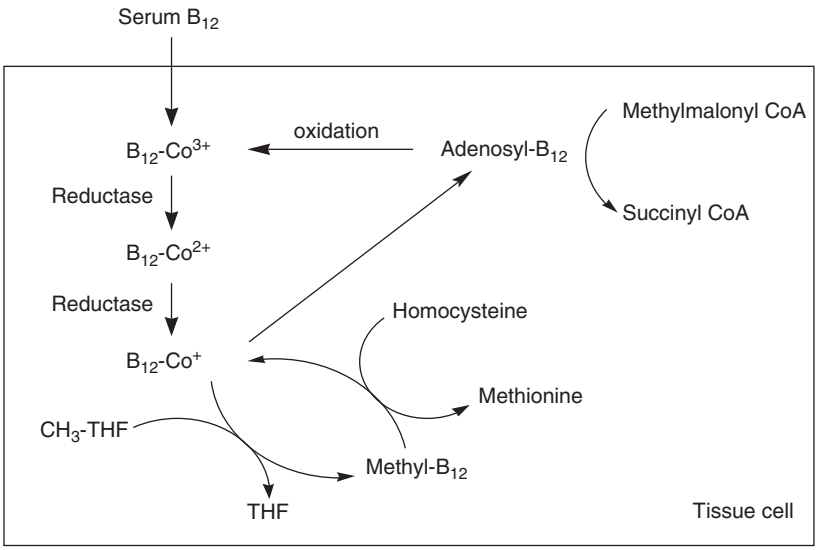

Figure 2 Mammalian intracellular reactions requiring cobalamin. Conversion of methylmalonyl CoA to succinyl CoA is mitochondrial and requires cobalamin in the form of adenosyl-B_{12}. Conversion of homocysteine to methionine is cytosolic and requires cobalamin in the form of methyl-B_{12}.

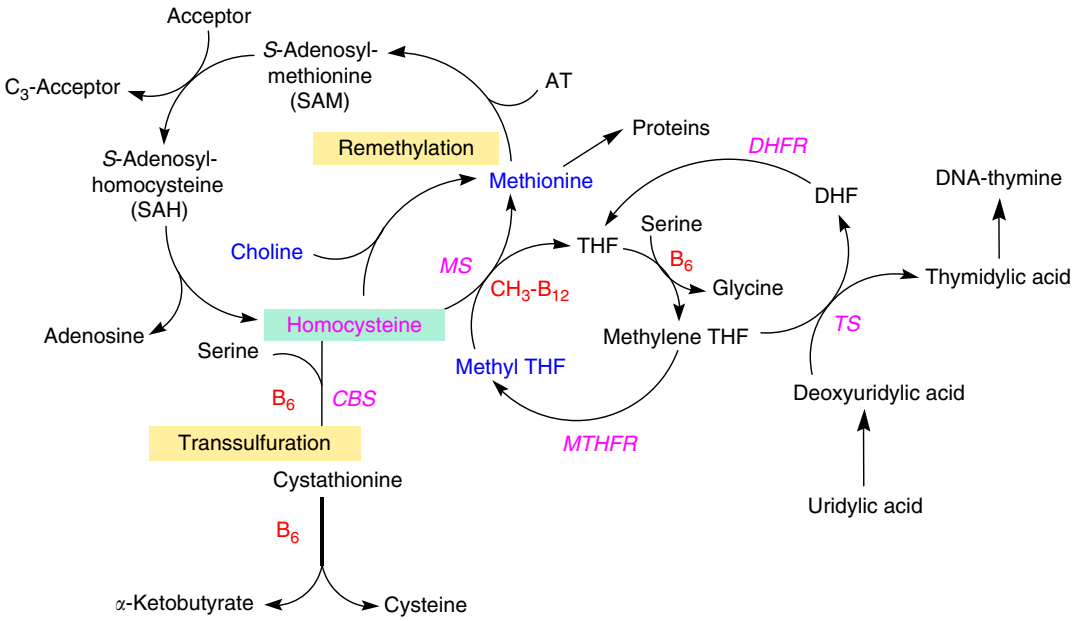

Figure 3 The remethylation and transsulfuration pathways of homocysteine metabolism showing the role of cobalamin in the form of methyl-B_{12} (CH_3-B_{12}) in the production of methionine. Other B vitamins (B_6, folate) and required enzymes for related pathways are shown. cobalamins found in nature. Cobalamins enter the food chain through herbivorous animals that harbor cobalamin-producing microorganisms in their upper gastrointestinal tract (e.g., the 'first stomach' of ruminants). Consumption of the meat or products of these animals supplies cobalamin in the diet for other animals. Dietary sources of cobalamin in humans are restricted to meat, poultry, fish, shellfish, eggs, and dairy products. Cobalamin is resistant to destruction by cooking, unlike the heat labile folates. On account of the exceedingly small daily requirement for cobalamin, in the order of 2–3 μg, and the relatively large body store of the vitamin (3000–5000 μg in individuals in developed countries), complete absence of intake or absorption of cobalamin is preceded by a long lag of up to 3–5 years before depletion of body cobalamin stores reaches a critical point that begins to result in the manifestations of cobalamin deficiency. This is not the case in developing countries where the onset of depletion may be much more rapid because of initially lower stores. Still, complete lack of dietary intake of cobalamin is somewhat rare and occurs only in strict vegans who shun all animal foods, including dairy products and eggs.

Cobalamin absorption is a complex mechanism that consists of several steps and involves several protein chaperones and receptors, defects of which can result in reduced or absent uptake of dietary cobalamin. The related and continuous processes of ingestion, digestion, and absorption of cobalamin comprising the assimilation of the vitamin are arbitrarily divided into six steps. During the first step of mastication and swallowing of food, dietary cobalamin becomes mixed with a binding protein derived from saliva belonging to the family of cobalamin-binding proteins known as haptocorrins. Cobalamin in foods is generally complexed to proteins that must first be digested to release the bioavailable vitamin. In the second step release of cobalamin takes place largely in the stomach, under the influence of gastric hydrochloric acid and proteolytic digestion by pepsin. It is during this process and in the acid environment of the stomach that salivary haptocorrin preferentially binds and protects food cobalamin. Another specific cobalamin-binding protein, known as intrinsic factor, is secreted by the parietal cells of the stomach, but is unable to bind the cobalamin still tightly complexed to haptocorrin. During the third step, which occurs in the duodenum, cobalamin is released from its complex with haptocorrin through the combined effects of pancreatic bicarbonate, which neutralizes the gastric acid, and the proteolytic action of the enzymes trypsin and chymotrypsin that digest haptocorrin and thus enable the binding of the free cobalamin by gastric intrinsic factor. In the fourth step, the intrinsic factor-cobalamin complex, having traversed the full length of the small intestine, arrives at the luminal surface of the terminal ileum. There, it comes in contact with specialized receptors. In the presence of calcium, the complex attaches to the receptor consisting of two distinct proteins coded by the genes cubulin and amnionless that is necessary to complete the assimilation process. Both proteins are essential for the internalization of the intrinsic factor-B_{12} complex through the process of receptor-mediated endocytosis. Through this process, cobalamin together with intrinsic factor is escorted by the receptor and taken into lysosomes. Here the intrinsic factor-cobalamin complex is released and intrinsic factor is degraded through the action of acid hydrolysis by lysosomal peptidases. The final fifth step is poorly understood but first involves the release from lysosomes and then the metabolism of cobalamin to its methyl and deoxyadenosyl derivatives. It is currently believed that cobalamin enters the plasma in the form of methylcobalamin. The assimilation of food containing

vitamin B_{12} is a lengthy process, as evidenced by the 6–8 h taken for orally administered cobalamin to first appear in the plasma and several additional hours for the process to be completed. Recent evidence indicates that cobalamin leaves the cell through an exit portal that is part of the ABC drug transport system, ABCC1 (also known as the Multidrug Resistance Protein, MRP1), present in the basolateral membrane of the intestinal epithelium as well as in other cells.

After cobalamin enters the plasma via the MRP1 it becomes bound to the cobalamin binding protein, transcobalamin (previously known as transcobalamin II to distinguish it from transcobalamins I and III which, together with the salivary cobalamin binding protein and other cobalamin binders present in secretions are now referred to collectively as the haptocorrins). The properties of transcobalamin and the haptocorrins are summarized in **Table 1**. The fraction of cobalamin bound to transcobalamin accounts for only 10–30% of the total plasma cobalamin. The major residual fraction of the plasma cobalamin is attached to haptocorrin. The function of haptocorrins is not known, but rapidly proliferating cells including bone marrow precursors can obtain cobalamin only from transcobalamin. Consequently, the critical fraction of the serum cobalamin is the transcobalamin-bound portion, known as holotranscobalamin. Conditions that alter the amount or distribution of cobalamin on these binding proteins can critically affect delivery and transport. Therefore, conditions that lead to an increase in haptocorrins, such as chronic granulocytic leukemia, characterized by markedly increased numbers of granulocytes (haptocorrins are produced in granulocytes), can give rise to an apparently normal serum cobalamin level even in patients who have severe underlying cobalamin deficiency, through redistribution of reduced body cobalamin stores. Conversely, insufficient holotranscobalamin can result in cobalamin deficiency even if the total serum cobalamin level is apparently normal. This occurs in infants and children affected by congenital transcobalamin deficiency, which is associated with severe megaloblastic anemia. Levels of transcobalamin may be affected by a number of factors. Lowering of holotranscobalamin can result in tissue cobalamin deficiency with a normal total serum cobalamin level. Now that sufficiently sensitive and robust methods are available to measure holotranscobalamin levels in serum, several studies have reported that there is a good inverse correlation between serum holotranscobalamin concentration and serum levels of the metabolites methylmalonic acid and homocysteine, which are described below.

Causes, Mechanisms, and Effects of Cobalamin Deficiency

There are several causes of cobalamin deficiency that range in severity and frequency of occurrence. These are summarized in **Table 2**. In general, causes of cobalamin deficiency can be

Table 1 Properties of human plasma cobalamin binding proteins

	Haptocorrins (TC I + III)	*Transcobalamin (TC II)*
Source	Granulocytes	Endothelial cells
Transport functions	Storage, excretion of B_{12} analogs, antimicrobial	Cellular B_{12} uptake
Binding specificity	Low specificity, binds B_{12} analogs	Binds B_{12} with higher specificity
Membrane receptors	Nonspecific asialoglycoprotein receptors on hepatocytes	Specific receptors on most cells
Saturation	High (mainly 'holo')	Low (mainly 'apo')
Fraction of total B_{12}	70–90%	10–30%
Plasma clearance	Slow ($t_{1/2} \sim 10$ days)	Rapid ($t_{1/2} \sim 6$ min)
Molecular Weight	60 000	38 000–45 000

Table 2 Causes of Vitamin B_{12} deficiency

1. Dietary[a]
   a. Veganism or very low intake of animal source foods
2. Gastric
   a. Atrophic gastritis and food B_{12} malabsorption
   b. Autoimmune gastritis/gastric atrophy (classical pernicious anemia)
   c. Extensive gastric disease or resection
3. Ileal
   a. Extensive ileal disease (Crohn disease, inflammatory bowel disease, tuberculous enteritis), or resection for these diseases
   b. Luminal disturbances (chronic pancreatic disease and gastrinoma) and parasites (giardiasis, bacterial overgrowth, and fish tapeworm).
4. Chemical/Drug
   a. Nitrous oxide
   b. PAS, metformin, colchicine
5. Congenital/Inherited
   a. Intrinsic factor deficiency/defect ('Juvenile' pernicious anemia).
   b. Intrinsic factor receptor deficiency/defect (Immerslund-Gräsbeck disease).
   c. Transcobalamin (TC) II deficiency or polymorphisms[a]
   d. Cobalamin mutants (C-G).

[a]Suboptimal cobalamin status caused by lowered intake or TC polymorphisms can predispose to more rapid onset of deficiency when other pathological causes of cobalamin deficiency occur.

divided into those caused by absent or markedly reduced dietary intake and those caused by malabsorption, either gastric or ileal. The most frequent cause of severe and clinically important cobalamin deficiency is pernicious anemia, caused by an autoimmune destruction of the gastric mucosa with consequent failure of intrinsic factor production. Less common causes include chemical inactivation and inherited defects in cobalamin absorption or metabolism.

In all situations resulting from impairment of cobalamin absorption, the time to onset of deficiency depends on several factors, including the size of the body store, the extent of impairment of absorption (partial or complete), and, in diseases like pernicious anemia and others affecting the small intestine, the rate of progression of the disease. In general, however, cobalamin deficiency resulting from malabsorption develops sooner than is the case in the dietary deficiency encountered among vegans. This difference may be explained by the existence of a considerable enterohepatic recirculation of cobalamin. Biliary cobalamin is efficiently reabsorbed in vegans compared with patients with pernicious anemia or other forms of malabsorption, because the intrinsic factor-dependent mechanism is intact.

Deficiency of cobalamin, when severe, affects all rapidly growing (DNA-synthesizing) tissues. After the marrow, the next most affected tissues are the epithelial cell surfaces of the gastrointestinal tract (mouth, stomach, and the small intestine). Affected cells are large, with increased numbers of multinucleated and apoptotic dying cells. The gonads are also affected and infertility occurs in patients with cobalamin deficiency. Cobalamin deficiency may also be associated with skin hyperpigmentation and has also been described in association with osteoporosis with reduced plasma bone-derived alkaline phosphatase and osteocalcin levels in the plasma.

Cobalamin deficiency may cause bilateral peripheral neuropathy or degeneration (demyelination) of the posterior and pyramidal tracts of the spinal cord and, less frequently, atrophy of the optic nerve or cerebral symptoms. Cobalamin-deficient patients typically display sensory disturbances (paraesthesiae), muscle weakness, difficulty in walking and sometimes dementia, psychotic disturbances or visual impairment. Long-term nutritional cobalamin deficiency in infancy leads to poor brain development and impaired intellectual development. The effects of cobalamin deficiency on the blood and on the nervous system may occur separately or in combination and their severity is often inversely rather than directly correlated. The biochemical basis for cobalamin neuropathy, however, remains obscure. Its occurrence in the absence of methylmalonic aciduria in TCII deficiency, and in monkeys given the anesthetic agent nitrous oxide, suggests that the neuropathy is related to a defect in homocysteine-methionine conversion. Accumulation of *S*-adenosylhomocysteine in the brain, resulting in inhibition of transmethylation reactions has been suggested as the mechanism.

Psychiatric disturbance is common in cobalamin deficiencies. Like the neuropathy, this has been attributed to a failure of the synthesis of SAM, due to reduced conversion of homocysteine to methionine. SAM is needed for methylation of biogenic amines (e.g., dopamine), as well as of proteins, phospholipids, and neurotransmitters in the brain.

Diagnosis of Cobalamin Deficiency

Cobalamin deficiency is suspected in individuals who display the typical manifestations of deficiency of the vitamin as described in the Section above, Causes, Mechanisms and Effects of Cobalamin Deficiency. In addition to the symptoms that may be experienced related to anemia (easy fatigue, shortness of breath, palpitations) and neuropathy (sensory and motor disturbances and memory loss) there are features that may be detected by a physician, including skin pallor (from anemia), abnormalities in neurological examination (sensory loss, abnormal balance and reflexes, and mental changes), and epithelial changes (skin pigmentation and smooth tongue). On the basis of any combination of such changes, cobalamin deficiency may be suspected but confirmation is necessary using laboratory tests because other conditions may give rise to effects that closely resemble cobalamin deficiency. The need to confirm suspected cobalamin deficiency applies also to individuals who have abnormalities in their blood count measurements.

The standard screening test for cobalamin deficiency consists of direct measurement of circulating levels of cobalamin. Serum levels less than 150p mol l^{-1} are considered deficient and levels 150–250p mol l^{-1} are considered borderline. Serum or plasma cobalamin concentration can be measured in several ways and this has evolved from early microbial growth assays through competitive binding assays that were first radioisotopic and are now enzyme linked or based on chemiluminescence detection. The sensitivity and specificity of these assays are imperfect, such that measurement of serum cobalamin levels does not always detect the presence of deficiency, nor does the finding of a low serum cobalamin always connote true deficiency. There are several reasons for this including the distribution of cobalamin between the binding proteins in circulation (**Table 1**), imperfections in the assays for its measurement, and various poorly understood factors relating to exchange of cobalamin between cellular and circulatory compartments. Regarding the distribution of cobalamin between plasma-binding proteins, because transcobalamin is responsible for cobalamin delivery to cells, the fraction of the total cobalamin that is associated with transcobalamin (holoTC), even though small in comparison with the haptocorrin-associated fraction, is more likely to be indicative of cobalamin status than is the total serum cobalamin. Some studies bear this out, although the clinical utility of measuring holoTC levels has not yet been convincingly demonstrated.

The other approach to identification of cobalamin deficiency is indirect, based on the detection of raised levels of compounds in the blood or urine that require adequate tissue levels of cobalamin for their metabolic disposal. The compounds most commonly measured for identification of possible cobalamin deficiency are methylmalonic acid and homocysteine. These are the substrates in two cobalamin-dependent reactions shown in **Figure 2**. Because of the identification of these metabolic roles for cobalamin, it has been apparent that deficiency of cobalamin or disturbances in its metabolism would result in accumulation of these substances and clinical assays for these metabolites is now available. Of the two compounds, elevation of the levels of methylmalonic acid is more specific for identification of cobalamin deficiency;

Table 3 Laboratory identification of cobalamin deficiency

Test	*Finding*	*Major limitations*
Serum/plasma cobalamin concentration	Low (<150 pmol l^{-1})	Normal levels in some deficient subjects; slight to moderately low levels may not connote deficiency
Serum/plasma holotranscobalamin (holo TC II)	Low (<35 pmol l^{-1})	Test not yet widely available; insufficient validation of usefulness
Serum/plasma or urine methylmalonic acid	Raised (>350 nmol l^{-1})	Levels raised in renal insufficiency
Plasma homocysteine	Raised ($>12\mu$mol l^{-1})	Levels raised in folate and in vitamin B_6 deficiencies, renal insufficiency, hypothyroidism

Table 4 Inherited disorders affecting cobalamin metabolism and their effects

Cobalamin protein	*Effects of deletion or mutation*
Intrinsic factor	Cobalamin malabsorption (juvenile pernicious anemia)
Cubulin/amnionless complex	Selective malabsorption of cobalamin, autosomal recessive megaloblastic Anemia (MGA1, Immerslund-Gräsbeck disease)
Transcobalamin	Severe cobalamin deficiency
Haptocorrin	No apparent abnormality
Cobalamin reducing and activating enzymes (mut$^+$ and mut-, cobalamin mutants C-G)	Varying degrees of disruption in one or both cobalamin-dependent pathways

however, renal insufficiency can cause raised levels of methylmalonic acid in the blood. In addition to cobalamin deficiency, several other conditions also can cause raised homocysteine levels in the blood, including deficiencies of folate and vitamin B6, lowered levels of thyroid hormone, and renal insufficiency.

Table 3 shows the idealized usefulness of the various tests commonly employed for the detection of cobalamin deficiency.

Inborn Errors of Cobalamin Metabolism

There are several known but rare inherited molecular defects resulting in absence or structural defects of proteins required for normal absorption, transport, or metabolism of cobalamin. These include the intestinal binding proteins, gastric intrinsic factor and its ileal receptor complex cubulin and amnionless, the plasma binders transcobalamin and haptocorrin, the enzymes that are required for conversion of cobalamin to its coenzymatically active methyl and deoxyadenosyl forms, and enzyme complexes involved in the catalysis of the two cobalamin-dependent reactions responsible for conversion of homocysteine to methionine and methylmalonate to succinate, respectively. Individuals who inherit a defective gene from each parent for any one of the proteins that are critical for cobalamin metabolism suffer from varying degrees of impairment of normal cobalamin-related status (see Table 4), closely mimicking the various manifestations of cobalamin deficiency described above. These disorders usually become manifest at an early age.

Glossary

Clinical deficiency Often results from severe prolonged tissue (nutrient) deficiency, which may in turn result from inadequate (nutrient) intake, but may also arise from impaired absorption, increased turnover and/or excretion; increased tissue demand, etc. Deficiency signs are directly observable; symptoms can be elicited by testing, and the response of these to intervention (e.g., nutrient supplementation) can help to confirm a diagnosis of deficiency.

Deficiency (clinical or biochemical) Arises when the amounts of an essential nutrient in (tissues of) the body falls below a critical minimum level. Biochemical (tissue) depletion then occurs, and may be followed by clinical (i.e., pathological) signs and symptoms of deficiency. Deficiency of an essential nutrient in the diet may lead to tissue- and clinical-deficiency, but impaired absorption, increased losses, increased tissue demands, etc., may also lead to a functional (tissue) deficiency, even when the diet-content is adequate.

Nutrient (e.g., vitamin) status Commonly assessed by measuring the concentration of the nutrient in an accessible body fluid such as serum or urine, or else the functionality of an enzyme or biochemical pathway (functional status). Published 'normal ranges' enable the results to be classified as (e.g.,) deficient, low, normal, or high.

Scurvy: The History and Discovery of Vitamin C

Scurvy is traditionally associated with long sea voyages, which often lasted for several years; the seamen's diets were confined to whatever could be stored at room temperature for long periods. In the absence of refrigeration, their diets typically consisted of dried biscuits and other dry cereal foods (wheat flour and oatmeal), salted meat, dried peas, cheese, butter, and ale, i.e., whatever could be dried and preserved in adverse tropical climates. The signs and symptoms described in classical accounts of scurvy, written long before its cause was understood, included lassitude, swollen joints, putrid and bleeding gums, failure of wound healing and the opening of old wounds and sores, intradermal bleeding due to capillary fragility, heart failure, and sudden death (Table 1). Although nowadays we distinguish the symptoms of true scurvy (now known to be produced specifically by vitamin C deficiency) from conditions such as beriberi (thiamin deficiency, associated with edema of the lower limbs), vitamin A deficiency (associated with night-blindness and corneal lesions), and rickets (vitamin D deficiency caused mainly by a lack of exposure to sunlight in children), in the older literature these conditions were often not recognized as distinct. Signs and symptoms of scurvy occurred on land in times of siege or during prolonged military campaigns where accesses to fresh foods were severely restricted. Although some medical practitioners and political leaders became convinced that scurvy had a dietary cause, and that its cure or prevention were possible by including fresh plant materials such as scurvy grass, decoctions of evergreen needles, etc., in the diet (Table 2), many believed, right up to the beginning of the twentieth century, that factors such as 'foul vapours or infections were to be blamed. Indeed, before the recognition and discovery of essential micronutrients in the early years of the twentieth century, which confirmed that small amounts of certain complex organic molecules are needed in the diet to maintain health; it was thought that food is needed to supply only energy, protein, certain minerals, and water.

Although treatments for scurvy stretch back over many centuries, a definitive dietary cure is attributable to James Lind, whose controlled intervention trial on board HMS Salisbury, followed by 'A Treatise of the Scurvy' in 1753, provided decisive evidence that persuaded the British Admiralty to insist on the inclusion of citrus fruit regularly in the British naval diet (Table 2). Lind showed that a 'rob' or decoction of

Table 1 Signs, symptoms, and biochemical indicators of vitamin C deficiency

Signs of clinical scurvy:
Bleeding gums and looseness of teeth.
Skin petechiae (intradermal bleeding due to capillary fragility); perifollicular hemorrhages; larger sheet hemorrhages, especially of the skin of the limbs and trunk; hematomas; purpura; bruising.
Ecchymoses (failure of eruption of hair from hair follicles); hyperkeratosis of hair follicles.
Breakdown and bleeding from previously healed wounds.
Swollen painful joints, with effusions and arthralgia; hemarthrosis; myalgia
Edema (especially pedal); dyspnea; dry eyes and mouth.
Abnormal long bone development in children; swelling ('beading') of rib cage; swelling of long-bone joints.
Intracranial hemorrhages in children; 'bulging eyes'; gums often affected if teeth already erupted.

Clinical symptoms of scurvy:
Fatigue, lassitude, joint pain, 'pithed frog' appearance in babies, for example, after prolonged feeding of condensed milk.
Abnormal X-ray appearance of long bones in children, especially at the epiphyses; subperiosteal bleeding; osteolysis; osteonecrosis.
Capillary fragility, as measured by the Hess test (pressure cuff on limb); nonspecific anemia in many cases.
Heart failure in severe cases, potentially leading to death.

Biochemical indicators of vitamin C deficiency:
Plasma vitamin C (ascorbate) concentrations $<11\ \mu$mol/l
Buffy coat vitamin C concentrations $<15\ \mu g/10^8$ cells
Suggested, but not yet verified, functional tests, for example, abnormalities of hydroxylation and cross-links of nascent collagen; of carnitine formation, of vitamin E recycling; of purine oxidation, etc.

oranges could rapidly cure the disease, and his discovery rapidly brought about dramatic reductions in the incidence and mortality due to scurvy.

In the first decade of the twentieth century, two Norwegian scientists, Holst and Frohlich, found that guinea pigs, like humans, reproducibly become scorbutic if fed a diet that lacks the 'antiscorbutic principle' which was, by now, known to be abundantly present in fresh fruit and vegetables. Few other mammals share this unusual dietary requirement, which, we now know, is solely attributable to the lack of a key enzyme, L-gulonolactone oxidase, which is needed in the multistep biosynthetic pathway for the synthesis of ascorbic acid from common sugars such as glucose and galactose. This animal model of dietary-induced scurvy provided a very important tool for the study of the disease.

Paradoxically, crystalline ascorbic acid (vitamin C) was first isolated, not from a well-established antiscorbutic plant source such as fruit or green leaves, but instead from an animal source, namely adrenal glands, where high concentrations of the vitamin are also found. Indeed, the original motivation for the isolation of the crystalline material (by Albert Szent-Gyorgyi in Gowland Hopkins' laboratory in Cambridge) was a serendipitous accident, arising out of his attempts to isolate a new adrenal hormone. Charles Glen King in Pittsburgh then showed that this easily-oxidized sugar derivative (initially named 'hexuronic acid') was indeed the long-sought antiscorbutic principle, i.e., vitamin C or L-ascorbic acid.

Table 2 Historical timeline of investigations into scurvy and discovery of vitamin C (ascorbic acid)

Tudor England: Leaders on certain long naval voyages successfully made use of plant foods (e.g., scurvy grass; young pine needles) as an *ad hoc* remedy for the prevalent scourge of scurvy.

Mid-eighteenth century: James Lind (a Scottish physician) carried out the first controlled trial of scurvy remedies at sea; he demonstrated efficacy of citrus fruit (oranges, lemons) and published 'Treatise of the Scurvy', 1753. Sir Gilbert Blane (end of eighteenth century) caused British naval diets to be supplemented with citrus (lemons, limes), thereby reducing prevalence of scurvy and greatly improving sailors' health – although limes eventually proved less effective than lemons, and scurvy reappeared as a result of failure to realise this.

Nineteenth century: Emergence of 'Barlow's disease' – scurvy in babies mainly fed with condensed milk.

Early twentieth century: Holst and Frohlich developed a guinea-pig model of scurvy, permitting investigation of the antiscorbutic potency of various foods.

1929: Albert Szent-Gyorgyi in Cambridge isolated 'hexuronic acid' from adrenal extracts, which proved identical to 'ascorbic acid', or 'vitamin C', the elusive antiscorbutic substance present in citrus fruit and plants, then being studied by Charles Glen King in Pittsburgh. 'Vitamin C' was thus isolated and named.

1930s: Norman Haworth and Tadeus Reichstein achieved chemical synthesis of vitamin C (ascorbic acid) from common sugars (glucose, galactose), thereby proving its chemical structure and elucidating its unique chemical and physiological (nutritional) properties.

1940s: Wartime studies showed that 10 mg vitamin C per day is sufficient to prevent and cure clinical scurvy in adult males.

Mid-twentieth century: Biochemical studies in several laboratories elucidated multiple roles of vitamin C: (1) as a cofactor for certain key enzymes, involved in specific oxidation and hydroxylation pathways of intermediary metabolism; (2) as a redox-modulator and provider of protection against certain types of (especially oxygen-radical-mediated) oxidative damage.

The vitamin was isolated in 1928, and its chemical structure was proven by de novo synthesis from common sugars a few years later (Table 2).

Degradation, Turnover, and Factors that Induce Increased Requirements for Vitamin C

The instability of vitamin C in air, and especially in neutral or alkaline aqueous solution, is attributable to the fact that in the presence of oxygen or other oxidizing agents it readily undergoes two successive one-electron oxidation steps to produce (reversibly, see below) another unstable product, dehydroascorbate, which readily undergoes an irreversible lactone ring-hydrolysis to yield 2,3-diketogulonic acid. Thus the vitamin is readily destroyed, both in foods during storage and (at a lower rate because of efficient recycling mechanisms) in the body. Diketogulonic acid is one of several degradation products of vitamin C that cannot be reconverted to the vitamin and are further degraded to stable excretory products, such as oxalic acid, by oxidative catabolism. Of all the micronutrients that are essential for human health and

survival, vitamin C is the most easily destroyed during drying and other traditional methods of preserving food. Citrus fruits contain other organic acids that inhibit this process of oxidation by lowering the pH of the fruit juice. This enables them, and extracts of them, to preserve at least some of their vitamin content for several weeks and even months of storage and thereby helps them to prevent and cure scurvy.

It remains largely a mystery why some people succumb to scurvy after a modest period of very low intake, whereas others survive for much longer. It has been speculated that some people may be able to produce all of the enzymes of the vitamin C synthetic pathway, including gulonolactone oxidase. However, this now seems unlikely and it is more probable that the retention and recycling mechanisms for the vitamin are more efficient in some people than in others. For example, smokers have a higher turnover of endogenous vitamin C than nonsmokers, mainly because of the free-radical oxidant species in cigarette smoke. People with infections also have increased vitamin C turnover, which is associated with the liberation of pro-oxidant substances (such as hypochlorous acid) that are used by the body to kill bacteria. Some people have genetic variants of the vitamin C transporters (see the following section); others have isoforms of certain blood proteins such as haptoglobins, both of which may be associated with relatively low levels of vitamin C in the blood. Very occasionally, there arise nonlethal mutations of vitamin C-dependent pathways whose abnormalities can be treated with high vitamin C intakes. A well-characterized example is Ehlers–Danlos syndrome, type VI, which is associated with impaired collagen lysyl hydroxylation and presents a variety of clinical and biochemical connective-tissue (collagen-related) defects. However, much more research is needed to determine, which of many possible genetic and environmental factors modulate the turnover of vitamin C in the body and to determine individual requirements and hence relative resistance to scurvy. Although 100–200 mg of the vitamins per day is needed to approach saturation of the tissues of humans, the amount needed to prevent or cure scurvy is less than 10 mg day^{-1}, as was shown by experiments involving prolonged periods of feeding with depleted diets in the middle of the twentieth century (**Table 2**). Today, overt clinical scurvy is rare. It is occasionally seen in refugee camps or in elderly people with poor diets that are devoid of the usual sources of the vitamin. The latter high-risk group contains many individuals who are unable to chew fresh fruit and vegetables because of poorly-fitting dentures or poor gastric tolerance of acidic or fibrous foods (see final section).

An essential dietary requirement for vitamin C is shared by only a small number of vertebrates, including most primates, guinea pigs and agoutis, and some birds and fishes. Most mammals synthesize the vitamin in their livers from hexose sugars; birds synthesize it in their kidneys. The final enzyme in the pathway, L-gulonolactone oxidase, has been lost in several unrelated species, suggesting a vulnerable and easily mutated locus on the genome. Presumably this mutation was neutral or advantageous during the natural selection of man's ancestors, when human and related-primate diets were rich in plant sources of the vitamin.

Well-Established Metabolic Functions of Vitamin C that are Impaired by Deficiency

Studies of guinea pigs (and other species that require a dietary source of vitamin C) have revealed that, when deprived of the vitamin, characteristic lesions of growing bones, failure of wound-healing of skin and bones, capillary defects, and other lesions arise, all of which point to a failure of the new synthesis of or repair processes for, connective tissues and especially the protein collagen, which is the major extracellular protein and comprises a third of all the protein in the body (**Table 2**). As the biochemical pathway of collagen biosynthesis became better understood, during the middle years of the twentieth century, it became clear that hydroxylated amino-acids, comprising two different hydroxylated forms of proline and one of lysine, occurred uniquely in collagen. These were not coded by the genome or inserted by the amino-acid-assembly machinery of the cell but instead were created by 'post-translational' amino-acid hydroxylation processes that took place after the nascent procollagen polypeptide chain had been synthesized on the polysomal messenger RNA. Some of the prolyl residues of the procollagen molecule were then hydroxylated to hydroxyprolyl residues, and some of the lysyl residues were hydroxylated to hydroxylysyl residues. The hydroxylated prolyl residues are essential for subsequent collagen triple-helix formation and hence for the secretion of nascent collagen; the hydroxylated lysyl residues form part of the essential pyridinoline-type crosslinks that stabilize the collagen fibers, especially those in bone. In the absence of sufficient vitamin C, these hydroxylation reactions rapidly fail, because the ferrous iron at the active center of the 'mixed function oxidase' enzymes that catalyze them is rapidly inactivated by oxidation. Vitamin C, specifically, is needed to keep the essential ferrous residues at the hydroxylase-enzyme active centers in the reduced, active, form. In the absence of the vitamin, these enzymes are inactivated only after a few cycles of hydroxylation. Hydroxyproline formation in the C1q component of complement, an important component of the immune system, is also vitamin C-dependent.

The essential function of vitamin C in collagen maturation can go a long way toward explaining many of the clinical lesions of scurvy (**Table 1**). However, the vitamin may also act directly on the transcription and translation of collagen mRNA and on the synthesis of other parts of the cell machinery that are needed for the formation of normal connective tissues.

Vitamin C plays a cofactor-like role in the reactions of several other enzymes that split molecular oxygen, notably members of the group of enzymes that are classified as 'mixed-function oxidases.' Two enzymes containing ferrous iron that are involved in carnitine biosynthesis (trimethyl lysine hydroxylase and γ-butyrobetaine hydroxylase) fall into this category. Aspartate β-hydoxylase, which is needed for the postsynthetic modification of protein kinase C, also requires vitamin C. Another enzyme that requires vitamin C is the copper-containing dopamine β-hydroxylase, and in the reaction that it catalyzes, ascorbic acid reduces cupric to cuprous copper at the active site. Peptidyl glycine hydroxylase (peptidyl α-amidase) is also a copper-containing enzyme requiring vitamin C as cosubstrate. Vitamin C can increase the activities of several other enzymes, usually by a nonspecific reducing or protective

action that is also shared by some other cellular reductants. Newly identified roles for the vitamin include cell-signaling; nucleic acid and histone dealkylation, and proteoglycan deglycanation (e.g., via turnover of glycipan-1, which is involved in cell growth and differentiation). One such newly identified ascorbate-dependent reaction is a dioxygenase-dependent hydroxylation of prolyl and asparaginyl residues in the α-subunit of hypoxia-inducible transcription factor 1 (HIF-1). The asparagine-hydroxylation modulates interaction with other activators, whereas the proline-hydroxylation targets HIF-1 for destruction in proteasomes; the unhydroxylated HIF-1 increases expression of most glycolytic enzymes and two glucose transporters (which also transport dehydroascorbate).

During its function, ascorbic acid is oxidized in two successive reversible one-electron steps, and most, if not all, of its essential biological actions are centered around this redox cycle. The first oxidation product is the free-radical form of the vitamin, which is known variously as 'monodehydroascorbate,' 'semidehydroascorbate,' or 'ascorbate free radical' (AFR). Although this intermediate shares with most other free radicals, the properties of having a relatively short half life and a high degree of chemical reactivity, it is more stable than many other free radicals, contrasting with the highly reactive and damaging radicals such as hydroxyl or superoxide radical that arise from molecular oxygen. By reacting with, and thus quenching, these damaging oxygen free radicals, ascorbate can act as a free-radical chain terminator and can thereby protect vulnerable macromolecules such as DNA, lipids, and proteins from oxidative damage by free-radical chain reactions. Such reactions would otherwise cause extensive damage, including genetic damage (to DNA), the formation of potentially atherogenic oxidized lipids, and oxidative inactivation of enzymes. For this reason, ascorbic acid is thought to possess important 'protective' antioxidant properties that are not directly connected with its other cofactor-like or cosubstrate-like roles in enzyme reactions. Ascorbate probably also protects host tissues against damage by oxidants such as hypochlorous acid that are produced in the normal course of bacterial-killing action of white cells.

The second one-electron oxidation step in ascorbate oxidation produces dehydroascorbate from the free-radical intermediate AFR. Both of these oxidized forms can be recycled to ascorbate either by nonenzymatic reactions with glutathione as the reductant (electron acceptor) or by pyridine nucleotide-dependent enzymatically catalyzed reactions. Thus, the two sequential one-electron oxidation steps from ascorbate to dehydroascorbate are fully reversible *in vivo*. However, the subsequent spontaneous nonenzymatic reaction comprising of hydrolysis of the 1,4-lactone ring is not reversible, so that the product of this reaction, diketogulonic acid, has no provitamin activity. Normally, approximately 3% of the vitamin C in the body is degraded every day and this loss must be replaced from the diet. Nevertheless, many weeks at or near zero intake are usually needed to reach scorbutic levels.

An important aspect of functional adequacy of nutrients is their efficient transport across cell membranes and hence between tissue pools. Reduced ascorbic acid is transported by two distinct sodium–vitamin C transporters, SVCT1, which is found mainly in epithelial tissue such as intestine, liver, and kidney and SVCT2, which is widely distributed among tissues. Naturally-occurring genetic variants affecting SVCT1 have recently been shown to affect circulating concentrations of the vitamin in human populations, and thus, presumably, vitamin C status and requirements. The oxidized form, dehydroascorbate, is transported by the glucose transporter systems, GLUT1 and GLUT2, and glucose and other sugars that share these transporters compete with it, a fact that is relevant for some diseases, such as diabetes, in which glucose transport and concentrations are abnormal.

Measurement of Vitamin C Status; Biochemical Tests for Adequacy and Deficiency

In species (such as humans) that cannot synthesize vitamin C in their bodies, the vitamin concentration in tissues and blood compartments (plasma, erythrocytes, and white blood cells) varies characteristically with the dietary intake of the vitamin. Because the blood-compartment concentrations mirror the concentrations in most other cells and tissue compartments, tissue vitamin C status can be monitored by measuring the concentration in plasma or blood, even though the blood intracellular concentrations are generally lower than those in most tissues. The concentration ratios between extracellular and various intracellular compartments are determined by active transport systems (SVCT 1 and 2, see previous section), that concentrate the vitamin inside many cell types. At high intakes of the vitamin, the intestinal absorption process is overwhelmed, so that some of the ingested vitamins remain unabsorbed and is destroyed in the lower intestine by intestinal bacteria. The maximum steady-state level in plasma can be temporarily exceeded following a high bolus intake, but the excess vitamin is rapidly excreted in the urine once the renal threshold for filtration and reabsorption is exceeded. These safety mechanisms limit the maximum concentration of the vitamin to which the tissues are normally exposed.

For many years, the best biochemical measure of vitamin C status was considered to be the buffy coat, or total white-cell concentration of the vitamin (**Table 1**), expressed as micrograms or micromoles per 10^8 white cells, the cell count in the assay sample being estimated by an electronic cell counter. This status index varied predictably with total body vitamin C stores during controlled (e.g., animal) depletion studies. However, in practice it has proved to be a difficult test to use in human studies and especially in surveys, as it requires complex laboratory operations to be performed immediately after collecting the blood. It is also difficult to harmonize this test between laboratories, and, because it measures the average vitamin C content across several different white-cell types, whose individual proportions and relative vitamin C contents may vary considerably, its interpretation was not always straightforward. In addition, infection affects the values obtained. For all of these reasons, this assay has fallen out of favor and is now rarely used. The concentration of the vitamin in erythrocytes or whole blood is not an ideal alternative, partly because hemoglobin can catalyze the oxidative destruction of the vitamin *in vitro* and partly because erythrocyte concentrations do not mirror other body compartments in a simple manner.

Serum or plasma vitamin C has therefore become the most commonly used status assay. To avoid short-term fluctuations caused by recent bolus intakes from food or supplements, it is preferable to collect an overnight-fasting blood sample. Because the vitamin is extremely easily oxidized, the sample must be carefully preserved unless the assay can be performed immediately. The usual approach is to add freshly prepared metaphosphoric acid, usually at between 2 and 5% w/v, which precipitates plasma proteins, chelates transition-metal ions, and provides a protective acidic environment of a suitable pH. If stored, the samples must be kept at a low temperature, for example, at $-25\,^{\circ}C$ for not more than a week or two or at $-80\,^{\circ}C$ for up to 1–2 years. There are many alternative physicochemical and chemical assay methods for measuring vitamin C in extracts of plasma or serum. These include (1) the measurement of its chemical reducing action on reducible dyes such as dichlorophenol indophenol or (2) the formation of either a colored osazone, or a fluorescent derivative with orthophenylene diamine, after conversion to dehydroascorbate. Quantitation by absorbance or by electrochemical detection after separation by high-performance liquid chromatography is favored by many workers. This procedure has the advantage of being relatively specific (i.e., free from most forms of interference) and highly sensitive, but it is more time-consuming than the simpler nonchromatographic methods. Different methods may differ with respect to their specificity and their sensitivity to problems of interference as well as in the precautions that are needed to avoid oxidative destruction of the vitamin during the assay. Careful validation and robust quality-control procedures are essential.

Plasma or serum levels below 11 μmol l^{-1} (<0.2 mg per 100 ml) are considered to be evidences of biochemical deficiency, and if this is severe and prolonged, the risk of clinical deficiency, i.e., scorbutic signs and symptoms, gradually increases. Intakes below 20 mg day^{-1} are likely to result in plasma levels in this range. Studies of human volunteers in the middle of the twentieth century showed clearly that an intake of 10 mg vitamin C per day in a healthy adult is sufficient to prevent clinical scurvy, and this small amount is also sufficient to cure scorbutic signs and symptoms (**Table 2**).

Assay methods based on urinary excretion of vitamin C have been used to study status, but they are too cumbersome and difficult to interpret to be useful in population studies. There are no well-established functional assays available to define vitamin C status and requirements at present. An older method known as the 'Hess test,' which measures relative capillary fragility under pressure or suction (**Table 1**), is useful only if subclinical scurvy is present and is rarely attempted today. Studies of collagen crosslinks or oxidative damage to macromolecules such as DNA or lipids may yield evidences about functional status in the future, but this remains a research challenge and is not yet an available option for routine studies or surveys.

Occurrence of Low Intakes and Poor Biochemical Status in Present-Day Societies

Although scurvy is rare, biochemical evidence of poor vitamin C status is not uncommon in certain high-risk groups in different human populations. Studies in The Gambia in West Africa, for instance, have shown that there is a regular seasonal cycle of availability of foods rich in vitamin C, with a good availability in the dry season alternating with a severe shortage during the rainy season. Plasma, buffy-coat, and breast-milk concentrations are all, on average, adequate in the dry season but are severely reduced during the rains. Functional and health-related parameters also deteriorate during the rains, but it has so far proved to be difficult to reverse this deterioration by vitamin C supplements alone. Therefore robust evidence of health consequences of this seasonal availability cycle has not yet been obtained.

From recent surveys in the UK, **Table 3** shows the prevalence of low intakes of vitamin C (estimated from the proportion of participants receiving less than the lower reference nutrient intake (LRNI), which is the amount deemed to be sufficient for only a few people in a population group, namely

Table 3 Prevalence of low vitamin C intakes and low plasma vitamin C concentrations in Britain at the end of the twentieth century

Age group	*LRNI(mg day^{-1})*	*Intake less than LRNI*	*Less than 11 μmol l^{-1} plasma vitamin*
Preschool 1.5–4.5 years	8	8/723 = 1.1%	24/723 = 3.3%
Young people 4–18 years			
4–10 years	8	1/423 = 0.2%	6/422 = 1.4%
11–14 years	9	0/307 = 0%	4/307 = 1.3%
15–18 years	10	1/271 = 0.4%	8/271 = 3.0%
Adults 19–64 years			
19–24 years	10	1/212 = 0.5%	11/151 = 7.3%
25–34 years	10	0/429 = 0%	8/307 = 2.6%
35–49 years	10	0/571 = 0%	8/414 = 1.9%
50–64 years	10	0/512 = 0%	8/366 = 2.2%
Adults 65 years and above			
Free-living 65–79 years	10	8/606 = 1.3%	88/606 = 14.5%
Free-living 80 + years	10	7/274 = 2.5%	45/274 = 16.4%
Institution-living	10	2/248 = 0.8%	98/248 = 39.5%

The LRNI is the Lower Reference Nutrient Intake, deemed to be sufficient for only that 2.5% of the population who have the smallest requirements, and a plasma concentration of 11 μmol l^{-1} is the cut-off for biochemical deficiency.

the 2.5% with the lowest requirements). Also shown in **Table 3** is the prevalence of plasma concentrations below the lower cut-off in normality, set at 0.2 mg dl^{-1} or 11 μmol l^{-1}. This is shown for several subgroups of the British population of different ages, from data collected in three nationally representative population surveys during the decade 1990s. It is clear from these results that a very few people were getting less than the LRNI for vitamin C over a 4 days or 7 days period of weighed-intake estimates of their diets. Low plasma levels were likewise relatively uncommon in the younger age groups; however, they were more common in older people and were especially prevalent, at almost 40%, in older people living in institutions such as nursing homes. Many of these relatively low plasma levels seen in frail older people are likely to be caused by factors other than very low intakes of the vitamin, such as reduced efficiency of the vitamin C transporters, especially SVCT1 or increased vitamin turnover. In the UK, unlike The Gambia, there was relatively little evidence of a major seasonal variation in vitamin C intake or status at the end of the twentieth century.

Vitamin C absorption does not appear to be abnormally low in healthy older people. However, the multiple pathologies associated with old age (and with debility at any age) are associated with increased turnover of the vitamin. Older people with very low levels of vitamin C are at higher risk of dying sooner than those with high levels, although short-term vitamin supplements generally fail to reverse this increased risk. It thus appears that vitamin C status can act as a barometer of health as well as being a marker of adequacy of vitamin C intake. Further research is needed to determine the key mechanisms that affect the rate of vitamin C turnover and its control in different age groups and different metabolic states. Because frail older people are at high risk of developing pressure sores and of needing surgery for a variety of ailments, there seems to be a potential public-health advantage in protecting vitamin C stores, especially in this vulnerable older age group.

Glossary

Carnitine β-Hydroxy-γ-trimethylammonium butyrate, biosynthesized by methylation of lysine, important for the transport of fatty acids into the mitochondrion for oxidation.
Flavoprotein Any enzyme (or other protein) with a prosthetic group formed from riboflavin (vitamin B_2) or one of its derivatives.
Glutathione A tripeptide, γ-glutamyl–cysteinyl–glycine that acts as a major redox cofactor, being oxidized to yield the hexapeptide lined by a disulfide bridge.
Granulocytes A class of white blood cells characterized by conspicuous cytoplasmic granules.
Hydroxymethylglutaryl CoA reductase The first and rate-limiting enzyme of cholesterol biosynthesis. The target of statin drugs for the treatment of hypercholesterolemia.
Hypercholesterolemia Elevated blood concentration of cholesterol.
Leukocytes White blood cells of various kinds.
Teleost fish Bony, as opposed to cartilaginous, fishes.

Introduction

Ascorbic acid is a vitamin (vitamin C) for only a limited number of species: human beings and other primates, bats, the guinea pig, a number of birds, and teleost fishes. In other species ascorbic acid is not a vitamin but is an intermediate in glucuronic acid catabolism, and its rate of synthesis bears no relation to physiological requirements for ascorbate. Species for which ascorbate is a vitamin lack the enzyme gulonolactone oxidase (EC 1.1.3.8) and have an alternative pathway for glucuronic acid metabolism, via reduction and the pentose phosphate pathway.

Ascorbic acid functions as a relatively nonspecific, radical-trapping antioxidant, and also reduces the tocopheroxyl radical formed by oxidation of vitamin E. It has a specific metabolic function as the coenzyme for dopamine β-hydroxylase and peptidyl glycine hydroxylase, and it is required to maintain the iron of 2-oxoglutarate-dependent hydroxylases in the reduced state. It also enhances the absorption of inorganic iron from foods.

Absorption, Transport, and Storage

In species for which ascorbate is not a vitamin, intestinal absorption is by sodium-independent facilitated diffusion, whereas in human beings and guinea pigs there is sodium-dependent active transport of the vitamin at the brush border membrane, with a sodium-independent mechanism at the basolateral membrane. Dehydroascorbate is absorbed passively in the intestinal mucosa, and is reduced to ascorbate before transport across the basolateral membrane.

At intakes up to about 100 mg day^{-1}, 80–95% of dietary ascorbate is absorbed, falling from 50% of a 1-g to 25% of a 6-g and 16% of a 12-g dose. Unabsorbed ascorbate is a substrate for intestinal bacterial metabolism.

Ascorbate and dehydroascorbate circulate in the bloodstream both in free solution and bound to albumin. Approximately 5% of plasma vitamin C is normally in the form of dehydroascorbate. Ascorbate enters cells by sodium-dependent active transport; dehydroascorbate is transported by insulin-dependent glucose transporters and is accumulated intracellularly by reduction to ascorbate. In poorly controlled diabetes mellitus, tissue uptake of dehydroascorbate is impaired because of competition by glucose, as well as insulin resistance or lack of insulin, which is required for activity of the transporters, and there may be functional deficiency of vitamin C despite an apparently adequate intake.

Approximately 70% of blood-borne ascorbate is in plasma and erythrocytes (which do not concentrate the vitamin from plasma). The remainder is in white cells, which have a marked ability to concentrate ascorbate; mononuclear leukocytes achieve 80-fold concentration, platelets 40-fold, and granulocytes 25-fold, compared with the plasma concentration.

There is no specific storage organ for ascorbate; apart from leukocytes (which account for 10% of total blood ascorbate), the only tissues showing a significant concentration of the vitamin are the adrenal and pituitary glands. Although the concentration of ascorbate in muscle is relatively low, skeletal muscle contains much of the body pool of 5–8.5 mmol (900–1500 mg) of ascorbate.

Metabolism and Excretion

As shown in **Figure 1**, oxidation of ascorbic acid proceeds by a one-electron process, forming monodehydroascorbate, which disproportionates to ascorbate and dehydroascorbate. Most tissues also contain monodehydroascorbate reductase (EC 1.6.5.4), a flavoprotein that reduces the radical back to ascorbate. In the cytosol dehydroascorbate is reduced by either reduced nicotinamide adenine dinucleotide (NADH) or reduced nicotinamide adenine dinucleotide phosphate (NADPH)-dependent enzymes; in mitochondria it is reduced by complex 3 of the electron transport chain. It is also reduced nonenzymically by reaction with glutathione. At neutral pH dehydroascorbate is unstable and is rapidly hydrated to diketogulonate, but little is lost in this way.

Both ascorbate and dehydroascorbate are filtered at the glomerulus, then reabsorbed by the same transporters as are involved in intestinal absorption; the sodium-dependent

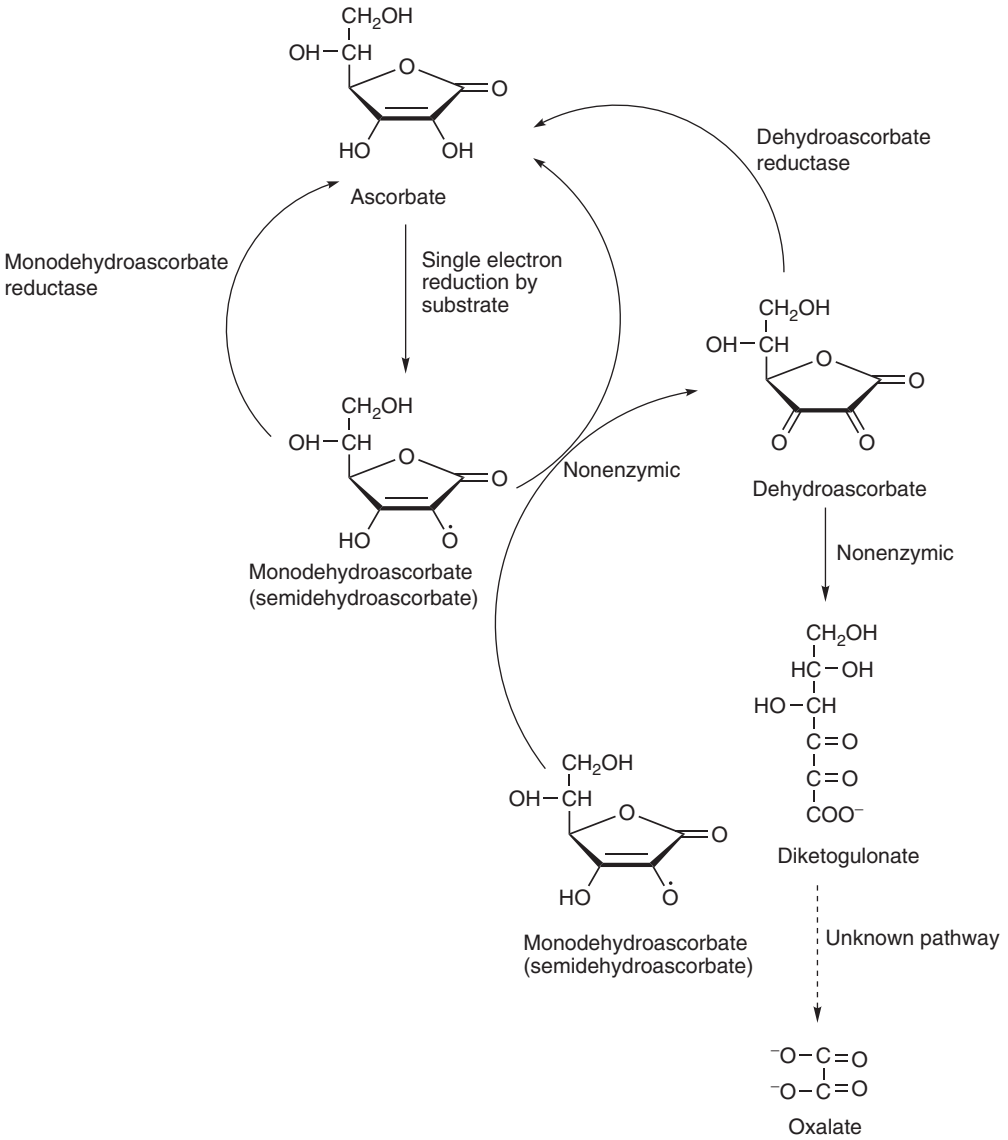

Figure 1 The metabolism of ascorbate.

vitamin C transporter for ascorbate and the glucose transporter for dehydroascorbate. When glomerular filtration exceeds the capacity of the transport systems, at a plasma concentration of ascorbate above about 85 μmol l^{-1}, the vitamin is excreted in the urine in amounts proportional to intake.

Approximately 1.5% of dietary ascorbate is excreted as oxalate; this may be a factor in development of oxalate renal stones. The pathway of oxalate formation from ascorbate is not known, and it is likely that there is nonenzymic cleavage of diketogulonate to oxalate. Ascorbate also increases the intestinal absorption of dietary oxalate.

Metabolic Functions of Ascorbic Acid

Ascorbic acid has specific and well-defined roles in two classes of enzymes: copper-containing hydroxylases and the 2-oxoglutarate-linked, iron-containing hydroxylases. It also increases the activity of a number of other enzymes *in vitro* – a nonspecific reducing action rather than reflecting a metabolic function of the vitamin. In addition, ascorbic acid has a number of less specific effects due to its action as a reducing agent and oxygen-radical quencher. There is also evidence that ascorbate has a role in regulating the expression of connective tissue protein (and some other) genes; its mechanism of action is unknown.

Copper-Containing Hydroxylases

Dopamine β-hydroxylase (EC 1.14.17.1) is a copper-containing enzyme involved in the synthesis of the catecholamines noradrenaline and adrenaline from tyrosine in the adrenal medulla and central nervous system. The active enzyme contains Cu^{+},

which is oxidized to Cu^{2+} during the hydroxylation of the substrate; reduction back to Cu^{+} specifically requires ascorbate, which is oxidized to monodehydroascorbate. In the chromaffin granules, monodehydroascorbate is reduced by transmembrane electron transport via cytochrome b_{561}, with electrons provided by ascorbate in the cytosol. The resultant monodehydroascorbate in the cytosol is reduced back to ascorbate by a mitochondrial outer membrane reductase.

More than half of the peptide hormones undergo postsynthetic modification to form a carboxyl terminal amide, which is essential for biological activity. One function of this amidation is to render the peptides more hydrophobic, and so enhance receptor binding. The amide group is derived from a glycine residue that is to the carboxyl side of the amino acid that will become the amidated terminal of the mature peptide. The reaction is catalyzed by peptidyl glycine hydroxylase (peptidyl α-amidase, EC 1.14.17.3).

The first step in the reaction is hydroxylation of the glycine residue to yield hydroxyglycine. The hydroxylase is a copper-containing oxygenase that uses ascorbate to reduce the two copper ions to Cu^{+}; these then activate oxygen, with incorporation of one atom into hydroxyglycine and reduction of the other to water. This is followed by the cleavage of the peptide bond, with amidation of the amino acid to the amino side of the hydroxyglycine residue, and release of glyoxylate. These two activities occur in a single bifunctional protein.

2-Oxoglutarate-Linked, Iron-Containing Hydroxylases

A number of iron-containing hydroxylases (listed in **Table 1**) share a common reaction mechanism, in which hydroxylation of the substrate is linked to decarboxylation of 2-oxoglutarate. Ascorbate is required for the activity of all of these enzymes, but it does not function as either a stoichiometric substrate or a conventional coenzyme (which would not be consumed in the reaction).

Proline and lysine hydroxylases are required for the postsynthetic modification of collagen, and proline hydroxylase also for the postsynthetic modification of osteocalcin in bone and the Cl_q component of complement, as well as a number of other proteins that have a collagen-like domain.

Aspartyl β-hydroxylase catalyzes hydroxylation of aspartyl and asparaginyl residues in epidermal growth factor (EGF) and a number of other proteins that have an EGF-like domain, including several of the vitamin K-dependent blood clotting factors.

Trimethyllysine and γ-butyrobetaine hydroxylases are required for the synthesis of carnitine, and many of the early signs of scurvy may be due to carnitine deficiency.

The best studied of this class of enzymes is procollagen proline hydroxylase; it is assumed that the others follow essentially the same mechanism. As shown in **Figure 2**, the first step is the binding of oxygen to the enzyme-bound iron, followed by attack on the 2-oxoglutarate substrate, resulting in decarboxylation to succinate, leaving a ferryl radical at the active site of the enzyme. This catalyzes the hydroxylation of proline, restoring the free iron to undergo further reaction with oxygen.

It has long been known that ascorbate is oxidized during the reaction, but not stoichiometrically with hydroxylation of proline and decarboxylation of 2-oxoglutarate. The purified enzyme is active in the absence of ascorbate, but after some 5–10 s (approximately 15–30 cycles of enzyme action) the rate of reaction falls. The loss of activity is due to a side-reaction of the highly reactive ferryl radical in which the iron is oxidized to Fe^{3+}, which is catalytically inactive – so-called uncoupled decarboxylation of 2-oxoglutarate. Activity is only restored by ascorbate, which reduces the iron back to Fe^{2+}.

Table 1 Vitamin C dependent, 2-oxoglutarate-linked hydroxylases

Aspartyl β-hydroxylase	EC 1.14.11.16
Histone demethylase	EC 1.14.11.27

Trimethyllysine hydroxylase	EC 1.14.11.8
γ-Butyrobetaine hydroxylase	EC 1.14.11.1

The Role of Ascorbate in Iron Absorption

Inorganic dietary iron is absorbed as Fe^{2+}, and not as Fe^{3+}; ascorbic acid in the intestinal lumen not only maintains iron in the reduced state but also chelates it, increasing absorption considerably. A dose of 25 mg of vitamin C taken together with a meal increases the absorption of iron approximately 65%, whereas a 1-g dose gives a ninefold increase. This is an effect of ascorbic acid present together with the test meal; neither intravenous administration of vitamin C nor supplements several hours before the test meal affects iron absorption, although the ascorbate secreted in gastric juice should be effective. This is not a specific effect of ascorbate; a variety of other reducing agents including alcohol and fructose also enhance the absorption of inorganic iron. In addition, ascorbate is the electron donor for the intracellular ferric reductase in intestinal mucosal cells.

Inhibition of Nitrosamine Formation

Oral bacteria can reduce nitrate to nitrite which, under the acidic conditions of the stomach, can react with amines in foods to form carcinogenic *N*-nitrosamines. In addition to dietary sources, a significant amount of nitrate is formed endogenously by the metabolism of nitric oxide – 1 mg per kg bodyweight per day (about the same as the average dietary intake), increasing 20-fold in response to inflammation and immune stimulation, and nitrate is secreted in saliva.

Ascorbate reacts with nitrite forming NO, NO_2, and N_2, so preventing the formation of nitrosamines. In addition to ascorbate in foods, there is considerable secretion of ascorbate in the gastric juice, and inhibition of gastric secretion for treatment of gastric ulcers, as well as reducing vitamin B_{12}

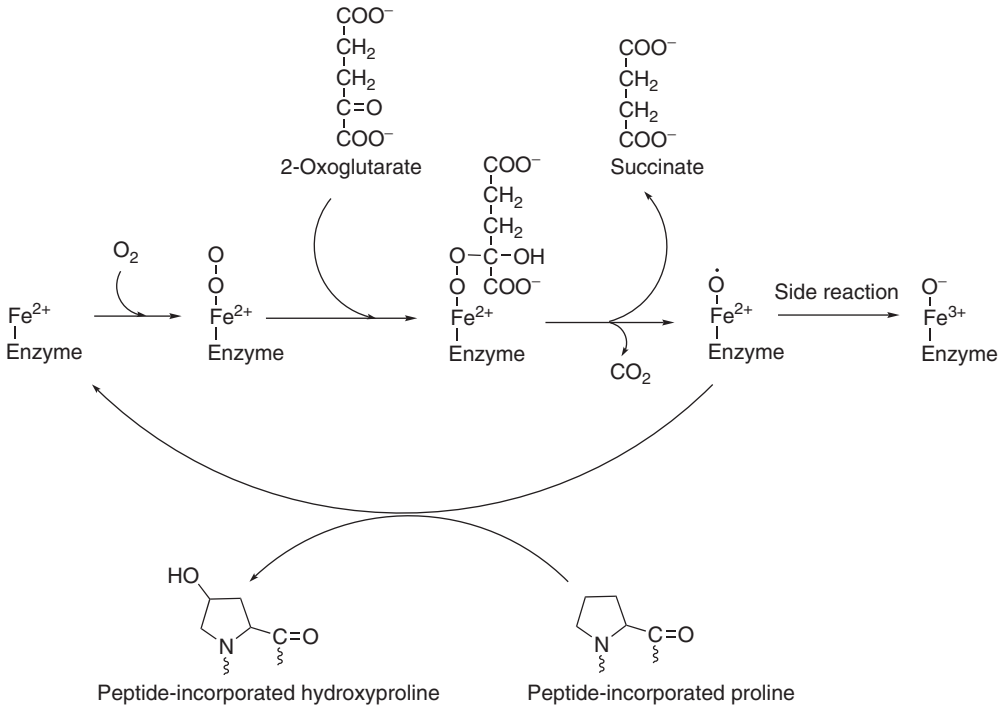

Figure 2 The reaction of procollagen proline hydroxylase.

absorption, also inhibits this presumably protective gastric secretion of ascorbate.

However, although ascorbate can deplete nitrosating compounds under anaerobic conditions, the situation may be reversed in the presence of oxygen. Nitric oxide reacts with oxygen to form N_2O_3 and N_2O_4, both of which are nitrosating reagents, and can also react with ascorbate to form NO and monodehydroascorbate. It is thus possible for ascorbate to be depleted, with little or no significant effect on the total concentration of nitrosating species.

Antioxidant and Prooxidant Actions of Ascorbate

Chemically, ascorbate is a potent reducing agent, both reducing hydrogen peroxide and also acting as a radical-trapping antioxidant, reacting with superoxide and a proton to yield hydrogen peroxide, or with the hydroxy radical to yield water. In each case the product is monodehydroascorbate, which, as shown in **Figure 1**, undergoes dismutation to ascorbate and dehydroascorbate. In studies of ascorbate depletion in men there is a significant increase in abnormalities of sperm deoxyribonucleic acid (DNA), suggesting that vitamin C may have a general, nonspecific radical-trapping antioxidant function.

Ascorbate also acts to reduce the tocopheroxyl radical formed by the oxidation of vitamin E in cell membranes and plasma lipoproteins. It thus has a vitamin E sparing antioxidant action, coupling lipophilic and hydrophilic antioxidant reactions.

The antioxidant efficiency of ascorbate is variable. From the chemistry involved, it would be expected that overall 2 mol of tocopheroxyl radical would be reduced per mole of ascorbate, because of the reaction of 2 mol of monodehydroascorbate to yield ascorbate and dehydroascorbate. However, as the concentration of ascorbate increases, the molar ratio decreases, and only at very low concentrations of ascorbate it tends toward the theoretical ratio. This is because, as well as its antioxidant role, ascorbate can be a source of hydroxyl and superoxide radicals.

At high concentrations, ascorbate can reduce molecular oxygen to superoxide, being oxidized to monodehydroascorbate. Both Fe^{3+} and Cu^{2+} ions are reduced by ascorbate, again yielding monodehydroascorbate; the resultant Fe^{2+} and Cu^{+} are reoxidized by reaction with hydrogen peroxide to yield hydroxide ions and hydroxyl radicals. Thus, as well as its antioxidant role, ascorbate has prooxidant action; the net result will depend on the relative rates of formation of superoxide and hydroxyl radicals by autooxidation and metal-catalyzed reactions of ascorbate, and the trapping of these radicals by ascorbate.

It seems likely that the prooxidant actions of ascorbate are of relatively little importance *in vivo*. Except in cases of iron overload there are almost no transition metal ions in free solution, they are all bound to proteins, and because the renal transport system is readily saturated, plasma and tissue concentrations of ascorbate are unlikely to rise to a sufficient extent to lead to significant radical formation

Assessment of Vitamin C Status

The early method of assessing vitamin C nutritional status was by testing the extent of saturation of the body's reserves, by giving a test dose of 500 mg (2.8 mmol), and measuring the amount excreted in the urine. In a subject with high status, more or less all of the test dose is recovered over a period of 5–6 h.

Table 2 Plasma and leukocyte ascorbate concentrations as criteria of vitamin C nutritional status

		Deficient	*Marginal*	*Adequate*
Whole blood	mmol l^{-1}	<17	17–28	>28
	mg l^{-1}	<3.0	3.0–5.0	>5.0
Plasma	mmol l^{-1}	<11	11–17	>17
	mg l^{-1}	<2.0	2.0–3.0	>3.0
Leukocytes	pmol per 10^6 cells	<1.1	1.1–2.8	>2.8
	μg per 10^6 cells	<0.2	0.2–0.5	>0.5

More sensitive assessment of status is achieved by measuring the concentration of the vitamin in whole blood, plasma, or leukocytes. Criteria of adequacy are shown in Table 2. The determination of ascorbate in whole blood is complicated by nonenzymic oxidation of the vitamin by hemoglobin, and most studies rely on plasma or leukocyte concentrations of ascorbate.

A problem arises in the interpretation of leukocyte ascorbate concentrations because of the different capacity of different classes of leukocytes to accumulate the vitamin. Granulocytes are saturated at a concentration of approximately 530 pmol per 10^6 cells, whereas mononuclear leukocytes can accumulate 2.5-times more ascorbate. A considerable mythology has developed to the effect that vitamin C requirements are increased in response to infection, inflammation, and trauma, based on reduced leukocyte concentrations of ascorbate in these conditions. However, the fall in leukocyte ascorbate can be accounted for by an increase in the proportion of granulocytes in response to trauma and infection (and hence a fall in the proportion of mononuclear leukocytes). Total leukocyte ascorbate is not a useful index of vitamin C status without a differential white cell count.

There is increased formation of 8-hydroxyguanine (a marker of oxidative radical damage) in DNA during (short term) vitamin C depletion, and the rate of removal of 8-hydroxyguanine from DNA by excision repair, and hence its urinary excretion, is affected by vitamin C status. This suggests that measurement of urinary excretion of 8-hydroxyguanine may provide a biomarker of optimum status, as a basis for estimating requirements.

Requirements

Although the minimum requirement for ascorbate is firmly established, there are considerable differences between the reference intakes published by different national and international authorities. Depending on the chosen criteria of adequacy, and assumptions made in interpreting experimental results, it is possible to produce arguments in support of reference intakes ranging from 30 to 100 mg day^{-1}. Studies of intakes associated with reduced risks of cancer and cardiovascular disease suggest an average requirement of 90–100 mg day^{-1}, and a reference intake of 120 mg day^{-1}.

Minimum Requirement

The minimum requirement for vitamin C was established in the 1940s in a depletion/repletion study, which showed that an intake of less than 10 mg day^{-1} was adequate to prevent the development of scurvy, or to cure the clinical signs. At this level of intake, wound healing is impaired, and optimum wound healing requires a mean intake of 20 mg day^{-1}. Allowing for individual variation, this gives reference intake of 30 mg day^{-1}, which was the UK figure until 1991 and the World Health Organization/Food and Agriculture Organization figure until 2001.

Requirements Estimated from the Plasma and Leukocyte Concentrations of Ascorbate

The plasma concentration of ascorbate shows a sigmoidal relationship with intake. Below approximately 30 mg day^{-1} it is extremely low and does not reflect increasing intake any significant extent. As the intake rises above 30 mg day^{-1}, the plasma concentration begins to increase sharply, reaching a plateau of 70–85 μmol l^{-1}, at intakes between 70 and 100 mg day^{-1}, when the renal threshold is reached and the vitamin is excreted quantitatively with increasing intake.

The point at which the plasma concentration increases more or less linearly with increasing intake represents a state where reserves are adequate and ascorbate is available for transfer between tissues. This corresponds to an intake of 40 mg day^{-1} and is the basis of the UK, EU, and FAO figures. At this level of intake the total body pool is approximately 5.1 mmol (900 mg). It has been argued that setting requirements and reference intakes on the basis of the steep part of a sigmoidal curve is undesirable, and a more appropriate point would be the intake at which the plasma concentration reaches a plateau, at an intake of approximately 100–200 mg day^{-1}.

The US/Canadian reference intakes of 75 mg for women and 90 mg for men are based on studies of leukocyte saturation during depletion/repletion studies.

Requirements Estimated from Maintenance of the Body Pool of Ascorbate

An alternative approach to estimating requirements is to determine the fractional rate of catabolism of total body ascorbate; an appropriate intake would then be that required to replace losses and maintain the body pool.

Clinical signs of scurvy are seen when the total body pool of ascorbate is below 1.7 mmol (300 mg). The pool increases with intake, reaching a maximum of approximately 8.5 mmol (1500 mg) in adults – 114 μmol (20 mg) per kg bodyweight. The basis for the 1989 United States Recommended Daily Amount (US RDA) of 60 mg was the observed mean fractional turnover rate of 3.2% of a body pool of 20 mg per kg bodyweight per day, with allowances for incomplete absorption of dietary ascorbate and individual variation.

It has been argued that a total body pool of 5.1 mmol (900 mg) is adequate; it is threefold higher than the minimum required to prevent scurvy, and there is no evidence that there are any health benefits from a body pool greater than 600 mg. The observed body pool of 8.5 mmol in depletion/repletion studies was found in subjects previously consuming a self-selected diet, with a relatively high intake of vitamin C, and

therefore might not represent any index of requirement. Assuming a total body pool of 5.1 mmol and catabolism of 2.7% per day, allowing for efficiency of absorption and individual variation gives a reference intake of 40 mg day^{-1}.

Because the fractional turnover rate was determined during a depletion study, and the rate of ascorbate catabolism varies with intake, it has been suggested that this implies a rate of 3.6% per day before depletion. On this basis, and allowing for incomplete absorption and individual variation, various national authorities arrive at a reference intake of 80 mg.

The rate of ascorbate catabolism is affected by intake, and the requirement to maintain the body pool cannot be estimated as an absolute value. A habitual low intake, with a consequent low rate of catabolism, will maintain the same body pool as a habitual higher intake with a higher rate of catabolism.

Dietary Sources and High Intakes

It is apparent from the list of rich sources of vitamin C in Table 3 that the major determinant of vitamin C intake is the consumption of fruits and vegetables; deficiency is likely in people whose habitual intake of fruit and vegetables is very low. However, clinical signs of deficiency are rarely seen in developed countries. The range of intakes by healthy adults in Britain reflects fruit and vegetable consumption: the 2.5 percentile intake is 19 mg day^{-1} (men) and 14 mg day^{-1} (women), whereas the 97.5 percentile intake from foods (excluding supplements) is 170 mg day^{-1} (men) and 160 mg day^{-1} (women). Smokers may be at increased risk of deficiency; there is some evidence that the rate of ascorbate catabolism is twofold higher in smokers than in nonsmokers.

There is a school of thought that human requirements for vitamin C are considerably higher than those discussed above. The evidence is largely based on observation of the vitamin C intake of gorillas in captivity, assuming that this is the same as their intake in the wild (where they eat considerably less fruit than under zoo conditions) and then assuming that because they have this intake, it is their requirement – an unjustified assumption. Scaling this to human beings suggests a requirement of 1–2 g day^{-1}.

Intakes in excess of approximately 80–100 mg day^{-1} lead to a quantitative increase in urinary excretion of unmetabolized ascorbate, suggesting saturation of tissue reserves. It is difficult to justify a requirement in excess of tissue storage capacity.

A number of studies have reported low ascorbate status in patients with advanced cancer – perhaps an unsurprising finding in seriously ill patients. One study has suggested, on the basis of an uncontrolled open trial, that 10-g daily doses of vitamin C resulted in increased survival. Controlled studies have not demonstrated any beneficial effects of high dose ascorbic acid in the treatment of advanced cancer.

High doses of ascorbate are popularly recommended for the prevention and treatment of the common cold. The evidence from controlled trials is unconvincing, and meta-analysis shows no evidence of a protective effect against the incidence of colds. There is, however, consistent evidence of a beneficial effect in reducing the severity and duration of symptoms. This may be due to the antioxidant actions of ascorbate against the oxidizing agents produced by, and released from, activated phagocytes, and hence a decreased inflammatory response.

Scorbutic guinea pigs develop hypercholesterolemia. Although there is no evidence that high intakes of vitamin C result in increased cholesterol catabolism, there is evidence that monodehydroascorbate inhibits hydroxymethylglutaryl CoA reductase, resulting in reduced synthesis of cholesterol, and high intakes of ascorbate may have some hypocholesterolemic action. There is limited evidence of benefits of high intakes of vitamin C in reducing the incidence of stroke, but inconsistent evidence with respect to coronary heart disease.

Table 3 Rich sources of vitamin C

	Portion (g)	*mg per portion*	*mg 100 g^{-1}*
Blackcurrants	80	160	200
Oranges	250	125	50

Regardless of whether or not high intakes of ascorbate have any beneficial effects, large numbers of people habitually take between 1 and 5 g day^{-1} of vitamin C supplements. There is little evidence of any significant toxicity from these high intakes. Once the plasma concentration of ascorbate reaches the renal threshold, it is excreted more or less quantitatively with increasing intake. However, ascorbate can react non-enzymically with amino groups in proteins, leading to glycation, as occurs in poorly controlled diabetes, and there is some evidence that diabetics who take vitamin C supplements are at increased risk of cardiovascular disease.

Because the rate of ascorbate catabolism increases with increasing intake, it has been suggested that abrupt cessation of high intakes of ascorbate may result in rebound scurvy, because of 'metabolic conditioning' and a greatly increased rate of catabolism. Although there have been a number of anecdotal reports, there is no evidence that this occurs.

VITAMIN D

Physiology, Dietary Sources, and Requirements

MF Holick, Boston University Medical Center, Boston, MA, USA

© 2013 Elsevier Ltd. All rights reserved.

Introduction

Vitamin D is a fat-soluble vitamin that is recognized for its importance for bone health. Vitamin D is neither a vitamin nor a nutrient because exposure to sunlight can provide the body's requirement for vitamin D. We take vitamin D for granted because it is casual exposure to sunlight that provides most humans with their vitamin D requirement. This recognition and the fortification of milk and other foods including some margarines, cereals, and orange juice with vitamin D have eradicated vitamin D deficiency rickets as a significant health problem for children in the US and countries that practise this fortification process. However, it is now recognized that both children and adults are at risk for developing vitamin D deficiency. The daily requirement for vitamin D is 400 IU day^{-1} for children 0–1 year, 600 IU day^{-1} for children over 1 year and all and adults <70 years old, and 800 IU day^{-1} for those >70 years. However, without adequate sun exposure, at least 1000 IU day^{-1} may be needed. Once vitamin D is formed in the skin or ingested in the diet, it enters the bloodstream and travels to the liver and kidney where it is hydroxylated on carbons 25 and 1 to form 25-hydroxyvitamin D (25(OH)D) and 1,25-dihydroxyvitamin D ($1,25(OH)_2D$), respectively. 25-Hydroxyvitamin D is the major circulating form of the vitamin that is measured to determine the vitamin D status of patients. 1,25-Dihydroxyvitamin D is the biologically active form of vitamin D that is responsible for maintaining calcium homeostasis and bone health. It is now recognized that vitamin D deficiency may increase the risk of many chronic diseases, including cancers of the breast, prostate, and colon, type I diabetes mellitus, multiple sclerosis, rheumatoid arthritis, and heart disease.

Origin and Structure of Vitamin D

As the industrial revolution began to take hold in Northern Europe in the fifteenth century, it was quickly associated with a new disease that caused severe growth retardation and bony deformities in young children (**Figure 1**). This disease was commonly known as rickets or 'English disease' and plagued the children of the industrialized cities in Europe and North America for more than 250 years. Although Sniadecki in 1822 and Palm in 1890 both recognized that it was lack of exposure to sunlight that was the likely cause of rickets in children, Huldschinsky, in 1919, was the first to prove that exposure of the skin to ultraviolet radiation could cure rickets. Within 2 years, Hess and Unger reported that exposure of several rachitic children to sunlight was adequate for curing this bone-deforming disease.

Steenbock and Black and Hess independently recognized that exposure of animals and their food to ultraviolet radiation imparted antirachitic activity. This led to the recommendation for the ultraviolet irradiation of foods as a means of fortifying them with vitamin D. This resulted in the addition of provitamin D to milk followed by ultraviolet irradiation. As soon as it was possible to commercially synthesize vitamin D in large quantities, it was added directly to milk and other foods.

The first vitamin D was isolated from the irradiation of the yeast sterol ergosterol (**Figure 2**). This vitamin D was thought to be identical to that produced in the skin of animals and humans. However, studies revealed that when vitamin D produced from yeast was fed to chickens, they were unable to utilize it and developed rickets. When chickens were fed natural vitamin D from fish liver oil, rickets was prevented. This led to the conclusion that vitamin D originating from yeast was different from that in fish liver oil and animal and human skin. In 1937, this mystery was solved when the structure of provitamin D from pig skin was determined. A structural analysis revealed that provitamin D derived from ergosterol differed from that derived from pig skin. The provitamin D (ergosterol; provitamin D_2) that came from yeast had a double bond between carbons 22 and 23 and a methyl group on carbon 24. The provitamin D in animal skin had a side chain that was identical to cholesterol, that is, it did not contain either a double bond or methyl group on carbons 22–23 and 24, respectively, and was identified as 7-dehydrocholesterol (provitamin D_3) (**Figure 2**). The vitamin Ds generated from ergosterol and 7-dehydrocholesterol were called ergocalciferol (vitamin D_2) and cholecalciferol (vitamin D_3), respectively.

Production of Vitamin D in the Skin

During exposure to sunlight, the ultraviolet B photons with energies between 290 and 315 nm are absorbed by provitamin D_3 (7-dehydrocholesterol) in the skin. This absorption results in a photolysis of the B-ring of provitamin D_3 resulting in the formation of previtamin D_3 (**Figure 3**). However, because previtamin D_3 is thermodynamically unstable, it quickly undergoes an isomerization (rearrangement) of its triple bond system to form vitamin D_3. This isomerization process is enhanced in skin cells because the previtamin D_3 is synthesized

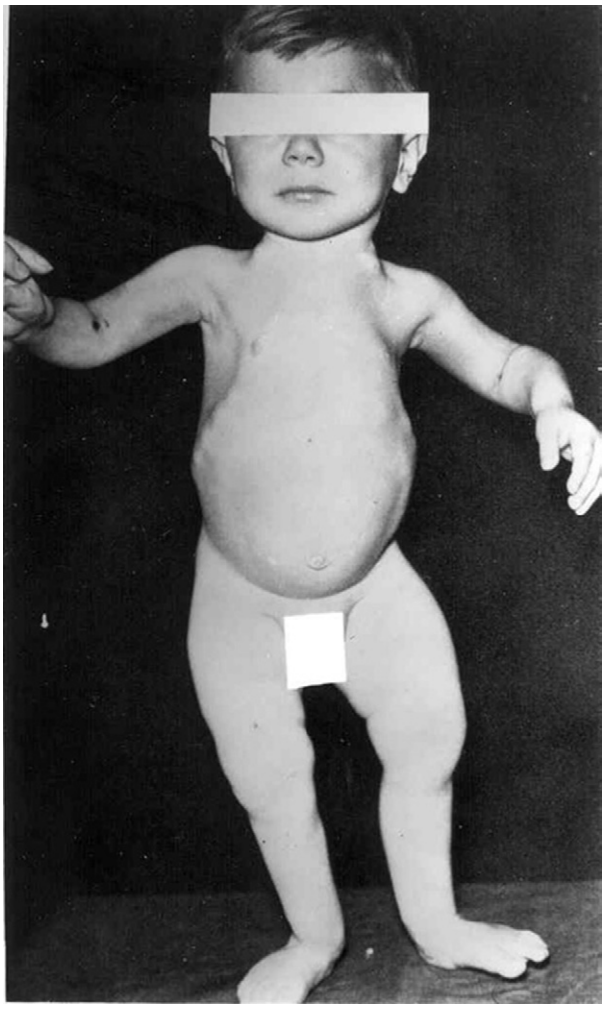

Figure 1 This is a typical presentation of a child with rickets. The child is suffering from severe muscle weakness, has bony deformities including bowed legs, and knob-like projects in the middle of his ribcage called the rachitic rosary. Reproduced from Fraser D and Scriver CR (1979) Disorders associated with hereditary or acquired abnormalities of vitamin D function: Hereditary disorders associated with vitamin D resistance or defective phosphate metabolism. In: De Groot LJ, *et al.* (eds.) *Endocrinology*, pp. 797–808. New York: Grune and Stratton.

in the cell membrane, which restricts its movement thereby accelerating the transformation of previtamin D_3 to vitamin D_3. Once vitamin D_3 is formed in the skin cell membrane, it is no longer restricted in its movement and freely translocates into the extracellular space to find its way into the dermal capillary bloodstream where it is bound to a specific vitamin D-binding protein (**Figure 3**).

An increase in skin pigmentation and zenith angle of the sun (change in latitude, season, and time of day) and the topical application of a sunscreen can markedly diminish or even prevent the production of vitamin D_3 in the skin. Over the age of ~65 years, there is a three- to fourfold decline in the synthetic capacity of the skin to produce vitamin D_3. Excessive exposure to sunlight cannot cause vitamin D_3 intoxication because once previtamin D_3 and vitamin D_3 are made in the skin, excessive quantities are rapidly destroyed by sunlight (**Figure 3**).

Absorption, Metabolism, and Excretion of Vitamin D

Vitamin D (vitamin D without a subscript represents either vitamin D_2 or D_3) is fat soluble and, therefore, once ingested vitamin D_2 and vitamin D_3 are incorporated into the chylomicron fraction and absorbed in the small intestine into the lymphatic system. Both dietary vitamin D_2 and vitamin D_3, and cutaneous vitamin D_3 enter the circulation and are bound to a specific α_1-globulin known as the vitamin D-binding protein (DBP). It is believed that this protein acts as a buffering system whereby it helps maintain circulating concentrations of 25(OH)D so that the free unbound form of 25(OH)D can enter into the renal tubular cells to be metabolized. 25-Hydroxyvitamin D bound to DBP is transported by megalin into the renal tubular cell where 25(OH)D is then dissociated from DBP and enters the mitochondria to be metabolized.

Neither vitamin D_2 nor vitamin D_3 possess any intrinsic biologic activity on calcium metabolism. They both require a hydroxylation on carbon 25 to form 25(OH)D (**Figure 4**). When given as a 1000-IU supplement, vitamin D_2 is as effective as vitamin D_3 in raising serum 25(OH)D levels. 25(OH)D is the major circulating form of vitamin D, and at physiologic concentrations, it too has little biologic activity on calcium metabolism. It must undergo a hydroxylation on carbon 1 in the kidney to form $1,25(OH)_2D$, the biologically active form of vitamin D (**Figure 4**). The metabolism of 25(OH)D to $1,25(OH)_2D$ is tightly regulated by parathyroid hormone (PTH), fibroblast growth factor 23 (FGF23), and serum phosphorus levels (**Figure 5**). PTH and low serum phosphorus levels increase the production of $1,25(OH)_2D$, whereas FGF23 suppresses its production.

25(OH)D and $1,25(OH)_2D$ act as substrate for a 24-hydroxylase (an enzyme that attaches an hydroxyl on carbon-24), which is found in the kidney and other target tissues for $1,25(OH)_2D$. Once $1,25(OH)_2D$ is hydroxylated on carbon 24, this is the first step in its degradation to a water-soluble acid, calcitroic acid (**Figure 4**). Vitamin D and calcitroic acid are excreted in the bile.

Biologic Functions of Vitamin D on Calcium Metabolism

$1,25(OH)_2D$ interacts with a specific nuclear receptor that is commonly known as the vitamin D receptor (VDR) and is one of the many members of the super family of steroid hormone receptors that includes retinoic acid, thyroid hormone, glucocorticoids, and sex steroids. Once $1,25(OH)_2D$ interacts with the VDR, the complex forms a heterodimer with retinoic acid X receptor (RXR) (**Figure 6**). This new complex sits on specific segments of vitamin D responsive genes known as vitamin D responsive elements (VDREs) to either increase or decrease transcriptional activity of the vitamin D-sensitive genes such as osteocalcin, calcium binding protein (calbindin), PTH, and osteonectin (**Figure 6**).

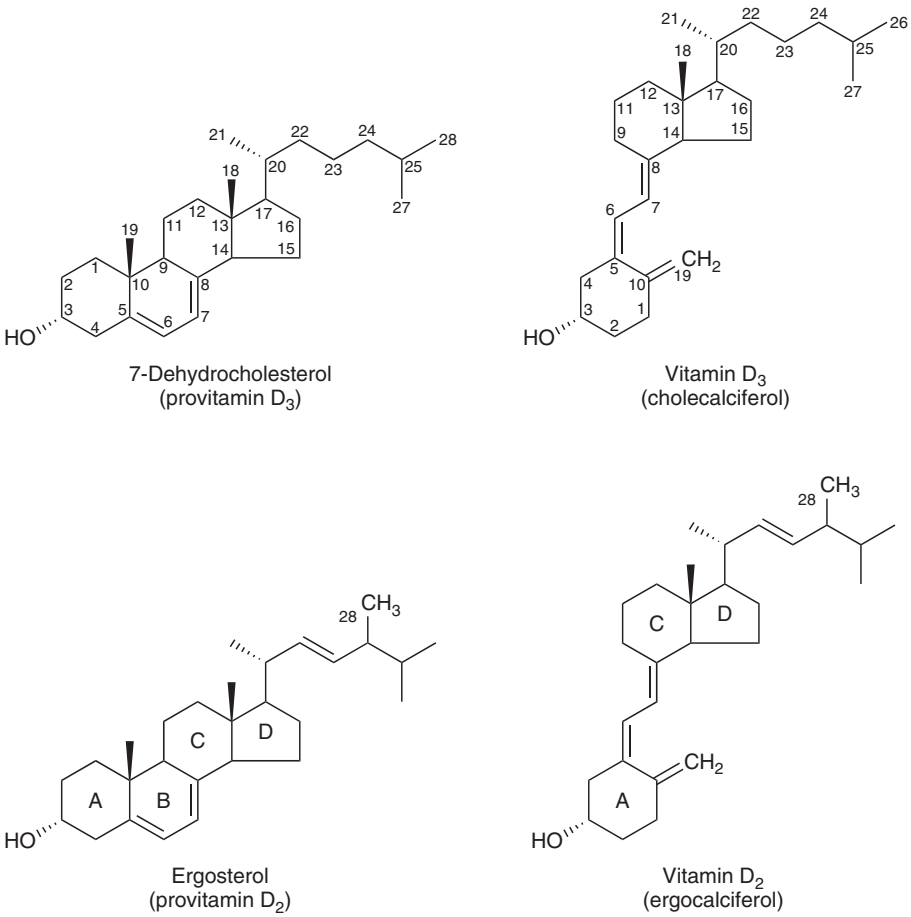

Figure 2 Structures for 7-dehydrocholesterol (provitamin D_3), ergosterol (provitamin D_2), vitamin D_3 (cholecalciferol), and vitamin D_2 (ergocalciferol). The carbons are numbered and the ring systems are labeled. Reproduced with permission from Holick MF (2007) Vitamin D deficiency. *New England Journal of Medicine* 357: 266–281.

In the intestine, $1,25(OH)_2D$ enhances the absorption of dietary calcium (from ~15% to 30–40% in adults) and phosphorus (from ~60–80%) across the microvilli of the small intestinal absorptive cells (Figure 5). $1,25(OH)_2D$ also interacts with osteoblasts to stimulate the expression for receptor activator NFκb ligand (RANKL) in the bone to initiate the transformation of monocytes into mature osteoclasts (Figure 5). Thus, $1,25(OH)_2D_3$ regulates serum calcium levels by enhancing the efficiency of intestinal calcium absorption and stimulating resorption of calcium from the bone. It remains controversial as to whether $1,25(OH)_2D$ has any direct action on the renal handling of either calcium or phosphorus.

There are a variety of other tissues including the brain, gonads, pancreas, stomach, activated T and B lymphocytes, monocytes, and skin that have nuclear VDR. Although the exact physiologic function of $1,25(OH)_2D$'s interaction with these VDRs is not well understood, it is known that *in vivo* and *in vitro* $1,25(OH)_2D_3$ can inhibit proliferation and induce terminal differentiation of various normal and tumor cells including normal human keratinocytes. This is the reason why activated vitamin D compounds are now routinely used for the treatment of the hyperproliferative skin disorder psoriasis. It has been estimated that at least 200 and as many as 2000 genes are influenced directly or indirectly by $1,25(OH)_2D_3$.

Evaluation for and Consequences of Vitamin D Deficiency

Vitamin D deficiency in young children causes rickets. As a child becomes vitamin D deficient, this results in a decrease in the efficiency of intestinal calcium absorption. There is a decline in blood-ionized calcium, which causes the parathyroid glands to produce and secrete more PTH. PTH tries to conserve calcium by enhancing tubular reabsorption of calcium in the kidney. However, in the face of developing hypocalcemia, which could disturb neuromuscular function and a wide variety of metabolic and cellular processes, the body calls upon $1,25(OH)_2D$ and PTH to stimulate the expression of RANKL in osteoblasts to mobilize monocytic stem cells to become functional osteoclasts, which, in turn, mobilize calcium from the skeleton (Figure 5). In addition, PTH causes a loss of phosphorus into the urine causing hypophosphatemia. Thus, in early vitamin D deficiency, the serum calcium is normal; it is the low serum phosphorus that causes the extracellular $CaXPO_4$ to be too low for normal mineralization of bone matrix. This causes a disruption in the orderly sequence of events in the differentiation of hypertrophied chondrocytes in the epiphyseal plates resulting in their disorganization causing a widening of the epiphyseal plates (end of long bones),

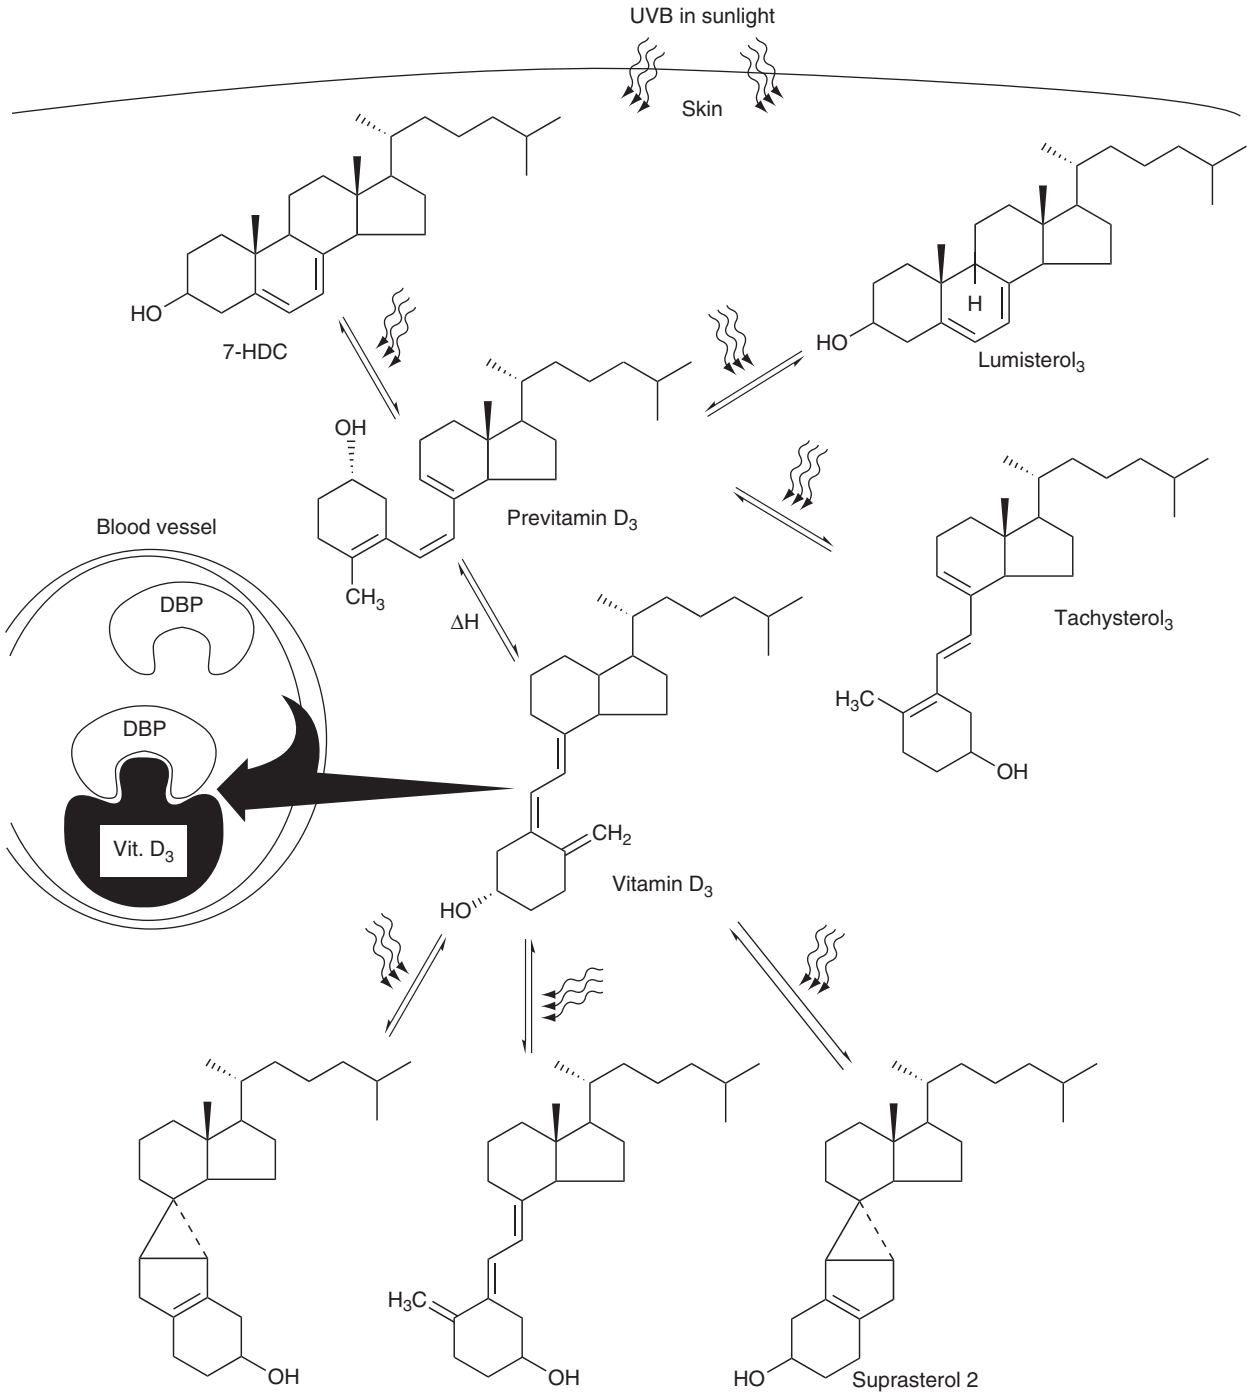

Figure 3 A schematic representation of the photochemical and thermal events that result in the synthesis of vitamin D_3 in the skin, and the photodegradation of previtamin D_3 and vitamin D_3 to biologically inert photoproducts. 7-Dehydrocholesterol (7-DHC) in the skin is converted to previtamin D_3 by the action of solar ultraviolet B radiation. Once formed, previtamin D_3 is transformed into vitamin D_3 by a heat-dependent (ΔH) process. Vitamin D_3 exits the skin into the dermal capillary blood system and is bound to a specific vitamin D-binding protein (DBP). When previtamin D_3 and vitamin D_3 are exposed to solar ultraviolet B radiation, they are converted to a variety of photoproducts that have little or no activity on calcium metabolism. Reproduced from Holick MF (1995) Vitamin D: Photobiology, metabolism, and clinical applications. In: DeGroot LJ, *et al.* (eds.) *Endocrinology*, 3rd edn, pp. 990–1013. Philadelphia: W.B. Saunders.

demineralization of the skeleton, and bony deformities (**Figure 1**).

Once the epiphyseal plates are closed later in adolescence, vitamin D deficiency can no longer cause bone deformities. Instead, there is an inability to mineralize newly deposited bone matrix leading to wide osteoid seams within the trabecular and cortical bone causing the bone disease commonly known as osteomalacia. In addition, the secondary

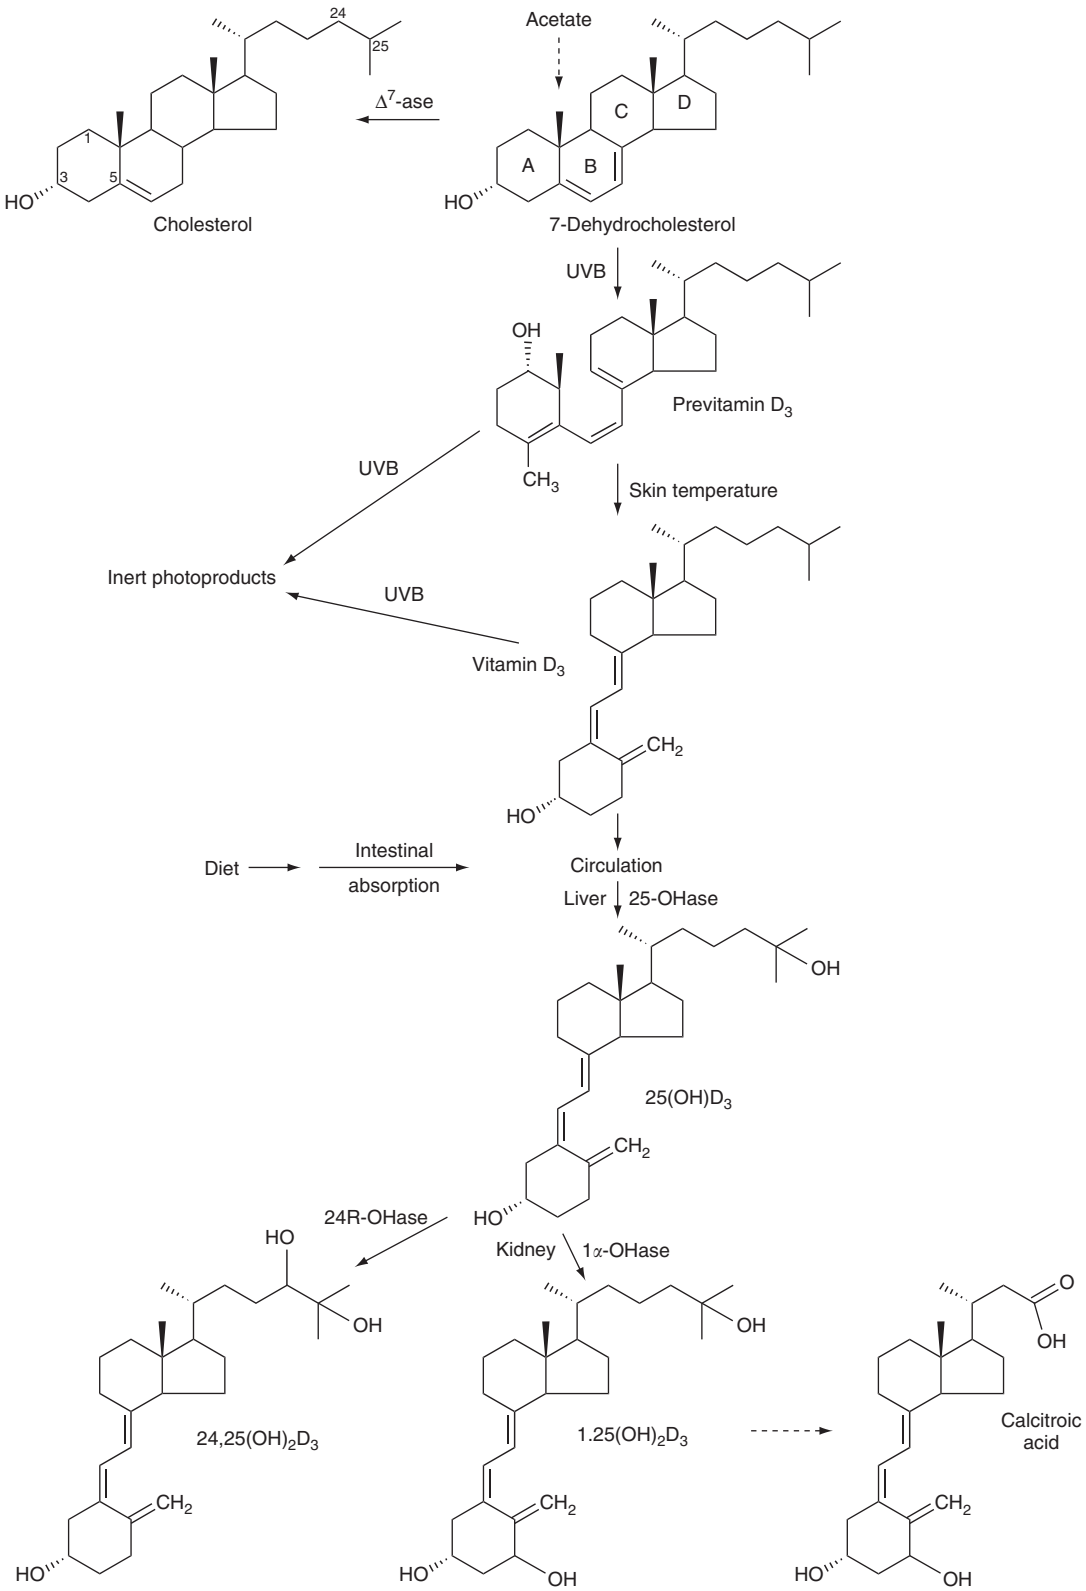

Figure 4 A schematic representation of the origin of vitamin D_3 and its metabolism in the liver by the hepatic vitamin D-25-hydroxylase. Once formed, the 25-hydroxyvitamin D_3 ($25(OH)D_3$) is metabolized by either a 25(OH)D-1α-hydroxylase or a 25(OH)D-24-hydroxylase. 1,25-Dihydroxyvitamin D_3 ($1,25(OH)_2D_3$) can either go to its target tissues to carry out its biologic function(s), or it can be metabolized in its side-chain and degraded to calcitroic acid. Reproduced from Holick MF (1995) Vitamin D: Photobiology, metabolism, and clinical applications. In: DeGroot LJ, *et al.* (eds.) *Endocrinology*, 3rd edn, pp. 990–1013. Philadelphia: W.B. Saunders.

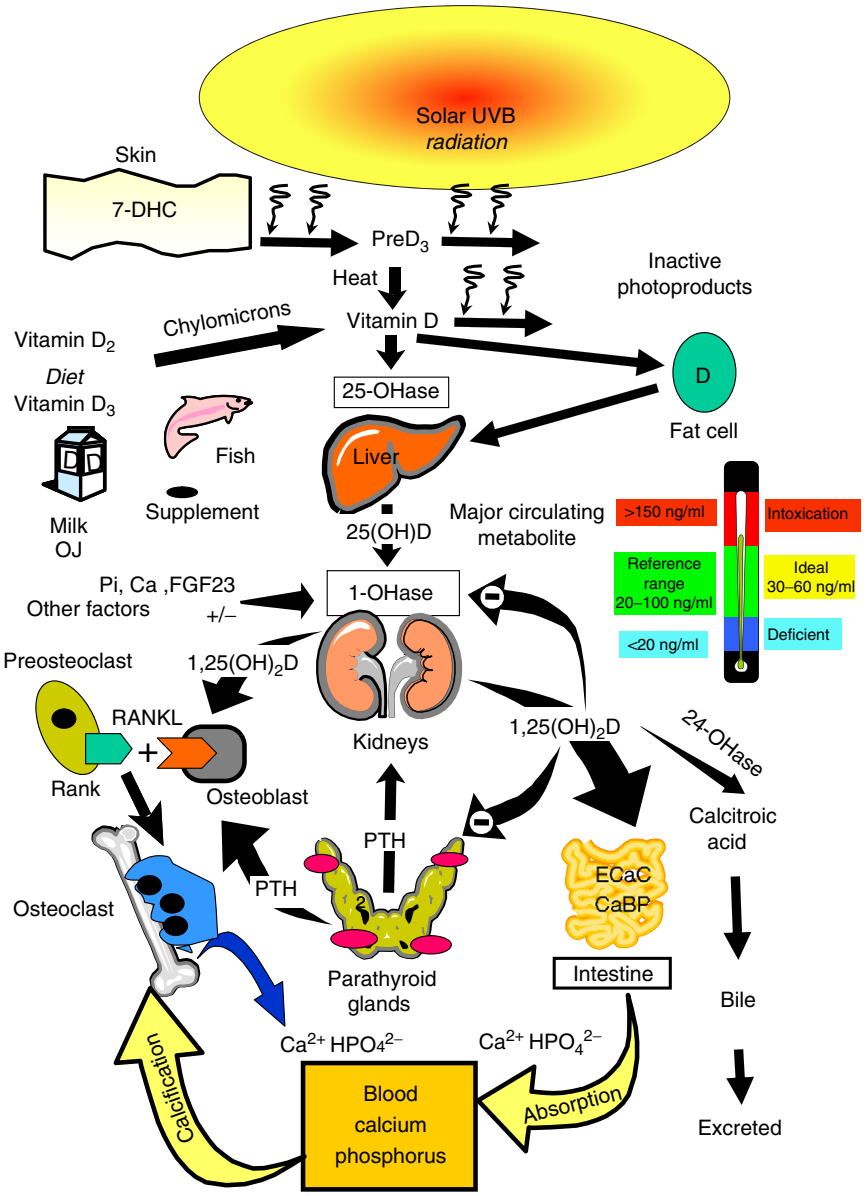

Figure 5 Schematic representation of the synthesis and metabolism of vitamin D for regulating calcium, phosphorus, and bone metabolism. During exposure to sunlight, 7-dehydrocholesterol in the skin is converted to previtamin D_3. $PreD_3$ immediately converts by a heat-dependent process to vitamin D_3. Excessive exposure to sunlight degrades previtamin D_3 and vitamin D_3 into inactive photoproducts. Vitamin D_2 and vitamin D_3 from dietary sources are incorporated into chylomicrons, transported by the lymphatic system into the venous circulation. Vitamin D (D represents D_2 or D_3) made in the skin or ingested in the diet can be stored in and then released from fat cells. Vitamin D in the circulation is bound to the vitamin D binding protein which transports it to the liver where vitamin D is converted by the vitamin D-25-hydroxylase to 25-hydroxyvitamin D (25(OH)D). This is the major circulating form of vitamin D that is used by clinicians to measure vitamin D status (although most reference laboratories report the normal range to be 20–100 ng ml^{-1}, the preferred healthful range is 30–60 ng ml^{-1}). It is biologically inactive and must be converted in the kidneys by the 25-hydroxyvitamin D-1α-hydroxylase (1-OHase) to its biologically active form 1,25-dihydroxyvitamin D [$1,25(OH)_2D$]. Serum phosphorus, calcium, fibroblast growth factors (FGF-23), and other factors can either increase (+) or decrease (−) the renal production of $1,25(OH)_2D$. $1,25(OH)_2D$ feedback regulates its own synthesis and decreases the synthesis and secretion of parathyroid hormone (PTH) in the parathyroid glands. $1,25(OH)_2D$ increases the expression of the 25-hydroxyvitamin D-24-hydroxylase (24-OHase) to catabolize $1,25(OH)_2D$ to the water-soluble biologically inactive calcitroic acid which is excreted in the bile. $1,25(OH)_2D$ enhances intestinal calcium absorption in the small intestine by stimulating the expression of the epithelial calcium channel (ECaC) and the calbindin 9 K (calcium binding protein; CaBP). $1,25(OH)_2D$ is recognized by its receptor in osteoblasts causing an increase in the expression of receptor activator of NFκB ligand (RANKL). Its receptor RANK on the preosteoclast binds RANKL which induces the preosteoclast to become a mature osteoclast. The mature osteoclast removes calcium and phosphorus from the bone to maintain blood calcium and phosphorus levels. Adequate calcium and phosphorus levels promote the mineralization of the skeleton. Reproduced with permission from Holick MF (2007) Vitamin D deficiency. *New England Journal of Medicine* 357: 266–281.

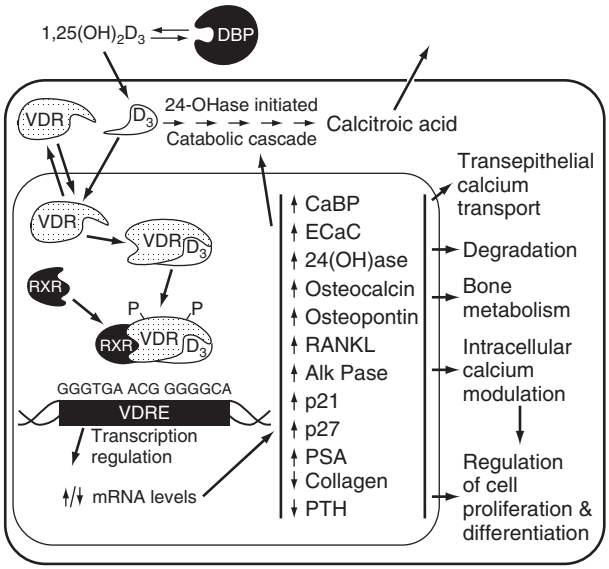

Figure 6 A schematic representation of the mechanism of action of $1,25(OH)_2D$ in various target cells resulting in a variety of biological responses. The free form of $1,25(OH)_2D_3$ enters the target cell and interacts with its nuclear vitamin D receptor (VDR), which is phosphorylated (Pi). The $1,25(OH)_2D$–VDR complex combines with the retinoic acid X receptor (RXR) to form a heterodimer, which, in turn, interacts with the vitamin D responsive element (VDRE), causing an enhancement or inhibition of transcription of vitamin D-responsive genes including calcium-binding protein (CaBP), ECaC, 24-OHase, RANKL, alkaline phosphatase (alk Pase), prostate-specific antigen (PSA), and PTH. Reproduced with permission from Holick MF (2007) Vitamin D deficiency. *New England Journal of Medicine* 357: 266–281.

hyperparathyroidism that results from vitamin D deficiency results in the mobilization of precious calcium stores from the bone thereby exacerbating bone loss and causing osteoporosis. This can increase a person's risk for fracture.

The hallmark for determining the vitamin D status is the measurement of the circulating concentration of 25(OH)D. The 25(OH)D is low or undetectable in vitamin D deficiency and markedly elevated in vitamin D intoxication. Measurement of $1,25(OH)_2D$ is of little value for determining the vitamin D nutritional status because its synthesis is tightly regulated. Indeed, as a person becomes vitamin D deficient, there is an increase in the secretion of PTH which, in turn, increases the production of $1,25(OH)_2D$. Thus, early in vitamin D deficiency one can see a normal fasting serum calcium, low-normal to low phosphorus, low 25(OH)D, and elevated PTH, $1,25(OH)_2D$ and alkaline phosphatase. In chronic vitamin D deficiency, all the above are seen with the exception that serum calcium and $1,25(OH)_2D$ are low-normal or low.

Nonskeletal Consequences of Vitamin D Deficiency

As early as 1941, it was appreciated that if you lived at higher latitudes in the US you were at higher risk of dying of cancer. A multitude of epidemiologic studies clearly show that if you live at higher latitudes and are more prone to vitamin D deficiency, then you are at higher risk of dying of colon, prostate, breast, ovarian, and a variety of other cancers. It is also known that living at higher latitudes increases risk of having high blood pressure and heart disease as well as autoimmune diseases including multiple sclerosis and type I diabetes.

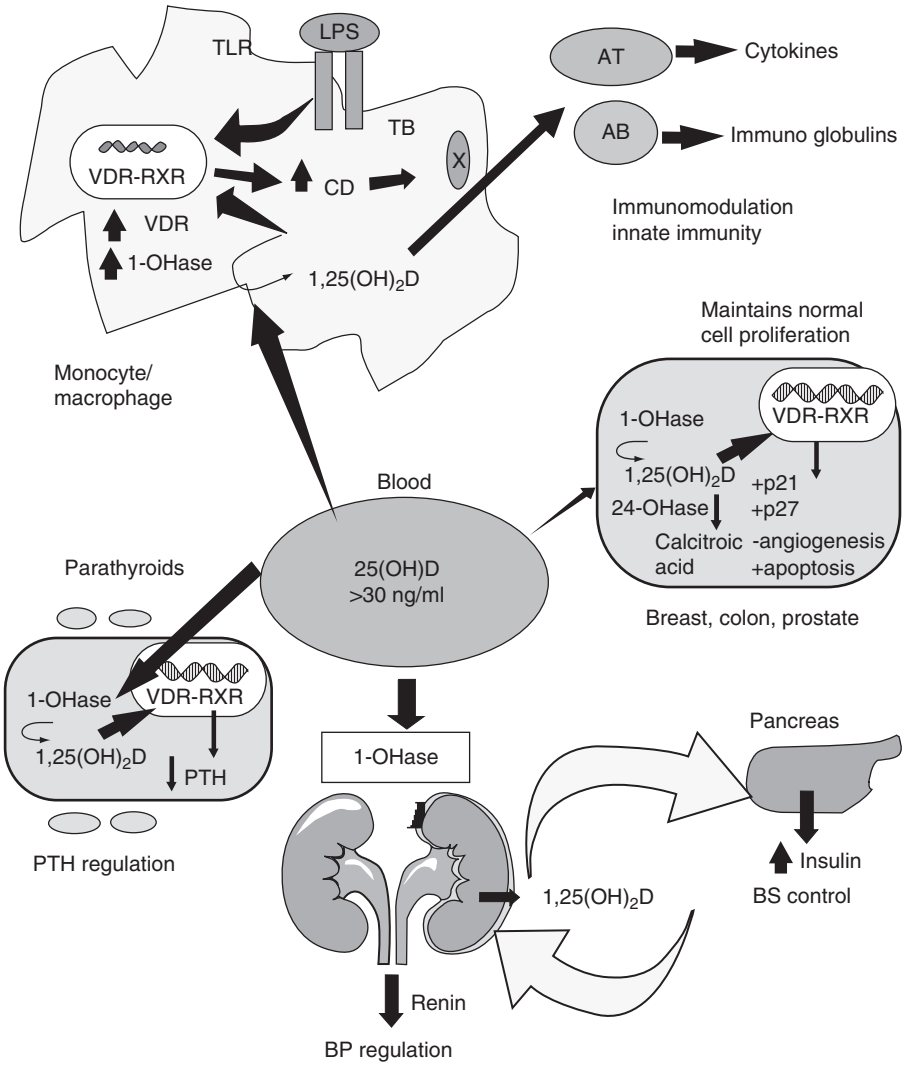
Essentially every cell and organ in the body requires vitamin D, that is, they all have a VDR. It is also known that most tissues in the body can activate vitamin D. Thus, maintaining adequate levels of 25(OH)D in the circulation of at least 20 ng ml^{-1} as recently recommended by the IOM for bone health and preferably 30 ng ml^{-1} may be necessary for various organs including colon, breast, and prostate to convert it to $1,25(OH)_2D$, which in turn can help regulate various genes responsible for cell growth and differentiation (Figure 7). This could be the explanation for how vitamin D sufficiency is protective against many common cancers. The immune cells also recognize $1,25(OH)_2D_3$. This may explain why children who had received 2000 IU of vitamin D a day during their first year decreased their risk of developing type I diabetes by 88%. A study in Japanese children who received 1200 IU vitamin D_3/d from December through March had a 42% reduced risk for developing influenza A infection compared to children who received a placebo pill. Increasing intake of vitamin D and sun exposure has now been associated with decreased risk of developing multiple sclerosis, rheumatoid arthritis, and even Crohn's disease.

The relationship of vitamin D to cardiovascular disease is finally being understood. $1,25(OH)_2D$ inhibits the production of the blood pressure hormone renin (Figure 7). It also alters cardiomyocyte growth and modulates the inflammatory response of atherosclerosis. Vitamin D deficiency has been associated with a 50% increased risk for having a heart attack and stroke, and 80% increased risk for developing peripheral vascular disease. When African-American teenagers were given 2000 IU vitamin D_3/d for 4 months, they had a significant reduction in arterial wall stiffness, a prelude to hypertension and artherosclerosis when compared to teenagers receiving 400 IU vitamin D_3/d for four months.

Recommended Dietary Intake of Vitamin D

Vitamin D is very rare in foods naturally, with the exception of fatty fish, some fish liver oils, and mushrooms exposed to UVR. Milk and some dairy products in the United States are fortified with vitamin D. Some orange juice and other juice products are fortified with calcium and 100 IU of vitamin D_3/8 oz. Multivitamin preparations that contain vitamin D are a good source of vitamin D as are pharmaceutical preparations (Table 1).

In 2010, the Institute of Medicine and the National Academy of Sciences reviewed the recommended dietary intake for calcium and vitamin D. The recommended dietary allowance (RDA) was defined as the daily intake level that is sufficient to meet nutrient requirements for nearly all (97–98%) individuals in life-stage and gender group. The RDA was meant to apply to individuals and not groups. When sufficient scientific evidence was not available to calculate an estimated average requirement (EAR), that is, a nutrient value that was estimated to meet the requirement defined by a specified indicator of adequacy in 50% of individuals in a life-stage and gender



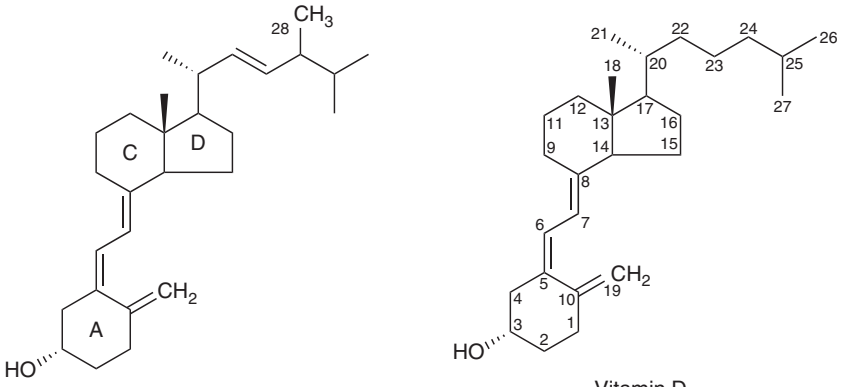


Figure 7 Metabolism of 25-hydroxyvitamin D (25(OH)D) to 1,25 dihydroxyvitamin D $1,25(OH)_2D$ for nonskeletal functions. When a monocyte/macrophage is stimulated through its toll-like receptor 2/1 (TLR2/1) by an infective agent such as mycobacterium tuberculosis (TB) or its lipopolysaccharide (LPS), the signal upregulates the expression of vitamin D receptor (VDR) and the 25-hydroxyvitamin D-1-hydroxylase (1-OHase). 25(OH)D levels >30 ng ml^{-1} provide adequate substrate for the 1-OHase to convert it to $1,25(OH)_2D$. $1,25(OH)_2D$ returns to the nucleus where it increases the expression of cathelicidin (CD) which is a peptide capable of promoting innate immunity and inducing the destruction of infective agents such as TB. It is also likely that the $1,25(OH)_2D$ produced in the monocytes/macrophage is released to act locally on activated T (AT) and activated B (AB) lymphocytes, which regulate cytokine and immunoglobulin synthesis, respectively. It is believed that the local production of $1,25(OH)_2D$ in the breast, colon, prostate, and other cells regulates a variety of genes that control proliferation including p21 and p27 as well as genes that inhibit angiogenesis and induced apoptosis. Once $1,25(OH)_2D$ completes the task of maintaining normal cellular proliferation and differentiation, it induces the 25-hydroxyvitamin D-24-hydroxylase (24-OHase). The 24-OHase enhances the metabolism of $1,25(OH)_2D$ to calcitroic acid which is biologically inert. Thus, the local production of $1,25(OH)_2D$ does not enter the circulation and has no influence on calcium metabolism. The parathyroid glands have 1-OHase activity, and the local production of $1,25(OH)_2D$ inhibits the expression and synthesis of PTH. The production of 1,25(OH)2D in the kidney enters the circulation and is able to downregulate renin production in the kidney and to stimulate insulin secretion in the β-islet cells of the pancreas. Reproduced with permission from Holick MF (2007) Vitamin D deficiency. *New England Journal of Medicine* 357: 266–281.

group, the Committee recommended using an adequate intake (AI). The AI is based on the observation of experimentally determined approximations of average nutrient intake by a defined population or subgroup that appears to sustain a defined nutritional state such as normal circulation nutrient values or growth. Because sunlight played such an important role in providing humans with their vitamin D requirement and, therefore, was a variable that was difficult to quantify in studies in infants that were reviewed by the Committee, it was concluded that an AI rather than an RDA should be used for vitamin D (Table 2).

Adequate Intake for Ages 0–6 Months

It is well documented that human and cows' milk has very little vitamin D naturally. Human milk contains on average

Table 1 Sources of vitamin D_2 and vitamin D_3

Source	*Vitamin D content (IU = 25 ng)*
Natural sources	 Vitamin D_2 (Ergocalciferol) Vitamin D_3 (Cholecalciferol)
Cod liver oil	~400–1000 IU/tsp vitamin D_3
Salmon, fresh wild caught	~600–1000 IU/3.5 oz vitamin D_3
Salmon, fresh farmed	~100–250 IU/3.5 oz vitamin D_3, vitamin D_2
Salmon, canned	~300–600 IU/3.5 oz vitamin D_3
Sardines, canned	~300 IU/3.5 oz vitamin D_3
Mackerel, canned	~250 IU/3.5 oz vitamin D_3
Tuna, canned	~236 IU/3.5 oz vitamin D_3
Shiitake mushrooms, fresh	~100 IU/3.5 oz vitamin D_2
Shiitake mushrooms, sun dried	~1600 IU/3.5 oz vitamin D_2
Egg yolk	~20 IU/yolk vitamin D_3 or D_2
Sunlight/UVB radiation	~20 000 IU equivalent to exposure to 1 minimal erythemal dose (MED) in a bathing suit. Thus, exposure of arms and legs to 0.5 MED is equivalent to ingesting ~3000 IU vitamin D_3
Fortified foods	
Fortified milk	100 IU/8 oz usually vitamin D_3
Fortified orange juice	100 IU/8 oz vitamin D_3
Infant formulas	100 IU/8 oz vitamin D_3
Fortified yogurts	100 IU/8 oz usually vitamin D_3
Fortified butter	56 IU/3.5 oz usually vitamin D_3
Fortified margarine	429/3.5 oz usually vitamin D_3
Fortified cheeses	100 IU/3 oz usually vitamin D_3
Fortified breakfast cereals	100 IU/serving usually vitamin D_3
Pharmaceutical sources in the US	
Vitamin D_2 (ergocalciferol)	50 000 IU/capsule
Drisdol (vitamin D_2) liquid	8000 IU/cc
Supplemental sources	
Multivitamin	400, 500, 1000 IU vitamin D_3 or vitamin D_2
Vitamin D_3	400, 800, 1000, 2000, 5000, 10 000, and 50 000 IU

[a]Designated calciferol which usually means vitamin D_2.

Source: Reproduced from Holick MF (2007) Vitamin D deficiency. *New England Journal of Medicine* 357: 266–281.

between 10 and 50 IU l^{-1} (0.25–1.25 μg). This is dependent on the mother's exposure to sunlight and her vitamin D intake. Several studies have suggested that infant intakes of vitamin D of between 8.5 (340 IU) and 15 μg (600 IU) day^{-1} would provide the maximum effect on their linear growth. A study in infants from Northern China (40–47° N) found that vitamin D supplements of 2.5 (100 IU), 5 (200 IU), or 10 μg (400 IU) day^{-1} resulted in 36, 29, and 2% of the infants being vitamin D deficient with 25(OH)D levels of less than 25 nmol l^{-1} (10 ng ml^{-1}). None of the infants, however, had manifestations of rickets. Chinese infants from two southern cities (22° N and 30° N) maintained normal vitamin D status on as little as 2.5 μg (100 IU) day^{-1} of vitamin D.

There was a seasonal variation of vitamin D status of infants when they were fed human milk only and did not receive vitamin D supplements; their 25(OH)D levels decreased in the winter due to less exposure to sunlight. However, this decrease did not occur in infants receiving a vitamin D supplement of 10 μg (400 IU) day^{-1} beginning at 3 weeks of age.

Table 2 Adequate intake (AI) and tolerable upper limit (UL) for Vitamin D

IOM Recommendations					*Dr Holick's recommendations for patients at risk for vitamin D deficiency*

Recommended adequate intakes (AI), estimated average requirement (EAR), recommended dietary allowance (RDA) and tolerable upper limit (UL) by the Institute of Medicine (IOM) and Dr. Holick's recommendation for Daily Allowance and safe Upper Limit (UL) for vitamin D for children and adults who are not obtaining adequate vitamin D from sun exposure and who are at risk for vitamin D deficiency.

Source: Reproduced from Holick MF, Binkley NC, Bischoff-Ferrari HA, *et al.* (2011) Evaluation, treatment, and prevention of vitamin D deficiency: an Endocrine Society Clinical Practice Guideline. *J Clin Endocrinol Metab* 96(7): 1911–1930.

Therefore, based on the available literature, it was concluded that a minimum intake of 2.5 μg (100 IU) day^{-1} of vitamin D was adequate to prevent rickets. However, at this intake and in the absence of sunlight, infants are at risk for developing hypovitaminosis D; therefore, it was recommended that an adequate intake of 10 μg day^{-1} (400 IU) was prudent for infants during their first 6 months of life.

Adequate Intake for Ages 6–12 Months

Infants between 6 and 12 months of age who were fed human milk and exposed to an average of 35 min day^{-1} of sunshine had similar 25(OH)D concentrations at 1 year of age whether the infants received 400 IU of vitamin D or no vitamin D supplementation. However, in Norway, in the winter, older infants who received an average of 5 μg (200 IU) day^{-1} of vitamin D had 25(OH)D levels that were intermediate between those of infants studied at the end of the summer and formula-fed infants.

Therefore, in the absence of any sunlight exposure, an AI of 10 μg (400 IU) day^{-1} was recommended.

RDA for Ages 1–18 Years

There are no studies in the scientific literature that systematically evaluated the influence of different amounts of vitamin D on either serum 25(OH)D or bone mineral content in this age group. Sunlight exposure is very important for this age group to obtain its required vitamin D. In South Africa, children aged 1–8 years of mixed race showed no evidence of vitamin D deficiency. A longitudinal study in Norway, where sun exposure was presumed to vary widely over a year, an intake of vitamin D of approximately 2.5 μg (100 IU) day^{-1} from fortified margarine in children aged 8–18 years was adequate to prevent vitamin D deficiency.

During puberty, there is a need to increase the efficiency of dietary calcium absorption in order to satisfy the rapid growth of the skeleton. As a result, there is an increase in the metabolism of 25(OH)D to $1,25(OH)_2D$. Because the blood levels of $1,25(OH)_2D$ are approximately 1000 times less than 25(OH)D, this increase in metabolism does not appear to increase the requirement of vitamin D for either boys or girls between the ages of 8 and 18 years. An average daily intake of 2.5 μg (100 IU) day^{-1} prevented any evidence of vitamin D deficiency in Scandinavian children in this age group. However, intakes less than 2.5 μg day^{-1} in Turkish children aged 12–17 years resulted in a decrease in 25(OH)D levels consistent with vitamin D deficiency. Girls of 9–17 years in Lebanon who took 2000 Iu day^{-1} for 1 year had better bone density and muscle strength compared to girls who received 400 IU vitamin D_3 per day. Therefore, based on the available literature, it appears that children between 1 and 18 years obtain some of their vitamin D from exposure to sunlight. The IOM recommended they ingest 15 μg (600 IU) day^{-1}.

RDA for Ages 19–70 Years

There is only sparse literature regarding the roles that sunlight and diet play in maintaining an adequate vitamin D status for men and women in this age group. This age group depends on sunlight for some of its vitamin D requirement. Regardless of exposure to sunlight, it was estimated by the IOM that 15 μg (600 IU) day^{-1} meets this age group's needs for bone health.

RDA for Ages 70+ Years

The IOM recommended increasing the dietary intake of vitamin D for this age group to 20 μg (800 IU) day^{-1}. This was based on several studies that demonstrated the importance of increasing dietary intakes of vitamin D to maximize bone health. There was strong evidence-based literature that demonstrated a decrease in the circulating concentration of 25(OH)D, and an increase in the PTH level correlated with an increased risk of skeletal fractures in both the hip and spine in this age group. Studies in both men and women supplemented with 10–25 μg day^{-1} of vitamin D demonstrated reduced bone resorption, increased bone mineral content, and a decrease in vertebral and nonvertebral fractures. An evaluation of 333 ambulatory Caucasian women (mean age 58 ± 6 years) found that serum PTH concentrations were elevated in the winter (between March and May) in women consuming less than 5.5 μg (220 IU) day^{-1} of vitamin D. There was no seasonal variation in serum PTH concentrations when vitamin D intakes were greater than 5.5 μg (220 IU) day^{-1}. When bone loss was evaluated between seasons in women (62 ± 0.5 years) who had a usual vitamin D intake of 2.5 μg day^{-1}, a dietary supplement of 10 μg day^{-1} decreased spinal and hip-bone density loss. An analysis of the skeletons of German adults at autopsy revealed no evidence of vitamin D deficiency osteomalacia for those who had a 25(OH)D >30 ng ml^{-1}.

Thus, because this age group does not obtain as much of its vitamin D from exposure to sunlight, it is at more risk for developing vitamin D deficiency. Therefore, in the absence of exposure to sunlight, there appears to be an increased requirement for vitamin D in this age group a RDA of 20 μg (800 IU) day^{-1} was recommended.

RDA for Pregnancy and Lactation

Although there is an increase in the metabolism of 25(OH)D to $1,25(OH)_2D$, during the last trimester of pregnancy and during lactation, the IOM concluded there is nothing in the evidence-based literature to suggest that there is an increased vitamin D requirement for pregnant and lactating women. Therefore, it was recommended that the RDA of vitamin D for pregnancy and lactation follows that recommended for their age group, that is, 15 μg (600 IU) day^{-1}. However, a study in Boston reported that 81% newborns and 76% of their mothers had a 25(OH)D <20 ng ml^{-1} even though they took a prenatal vitamin supplement containing 400 IU and drank two glasses of milk per day thereby ingesting 600 IU day^{-1}.

Healthy Vitamin D Intakes

There have been a multitude of studies during the past decade that suggest that the RDAs recommended for vitamin D may still be inadequate if there is no exposure to sunlight. Based on a multitude of studies, it is reasonable for children and adults

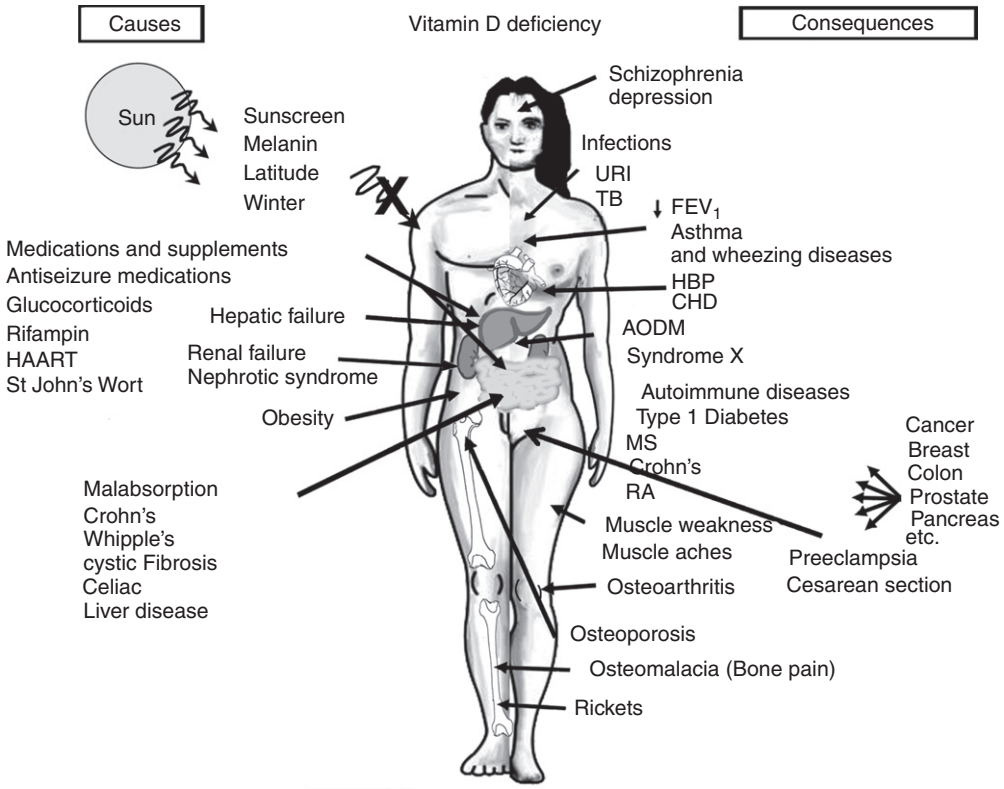

Figure 8 A schematic representation of the major causes for vitamin D deficiency and potential health consequences. Reproduced with permission from Holick MF (2010) *The Vitamin D Solution*. New York: Hudson Street Press.

to increase their vitamin D intake as noted in **Table 2**. In order to maintain a blood level of 25(OH)D >30 ng ml^{-1} and not to exceed 100 ng ml^{-1} for all the potential health benefits of vitamin D (**Figure 8**).

Tolerable Upper Intake Levels and Vitamin D Intoxication

An excessive intake of vitamin D can lead to vitamin D intoxication. This is characterized by a marked increase in serum 25(OH)D that is usually greater than 375 nmol l^{-1} (150 ng ml^{-1}) and is associated with hypercalciuria and hypercalcemia. This can lead to soft tissue calcification and increased risk of kidney stones. The safe upper limits for vitamin D, as recommended by the IOM, are found in **Table 2**.

Vitamin D intoxication usually occurs when a person ingests more than 10 000 IU of vitamin D daily for several months. A person does not need to be concerned about becoming vitamin D intoxicated if they take a multivitamin that contains 400 IU of vitamin D, drink a quart of milk that contains 400 IU of vitamin D, and is exposed to sunlight. The IOM recognized that vitamin D is not as toxic as once believed and raised the upper limit (UL) for older children and adults up to 4000 IU day^{-1}. Based on the evidence-based literature, these recommendations are conservative and could probably be raised up to 10 000 IU day^{-1} (**Table 2**).

Glossary

α-Tocopherol transfer protein (α-TTP) The hepatic α-TTP preferentially facilitates secretion of α-tocopherol, specifically 2R-α-tocopherols, not other tocopherols or tocotrienols, from the liver into the plasma.

Ataxia with vitamin E deficiency Humans with a defect in the α-TTP gene, who are not supplemented with vitamin E, display a syndrome called ataxia with vitamin E deficiency (AVED).

Biologic activity A term that has been used historically to indicate a disconnect between vitamin E antioxidant activities and *in vivo* activities.

Fat malabsorption syndromes Fat malabsorption syndromes are various disorders that cause an inability to absorb dietary fat. These can include cystic fibrosis, short bowel syndrome, or cholestatic liver disease, as examples.

Vitamin E metabolites Tocopherols, as well as tocotrienols, are metabolized to carboxyethyl hydroxychromans (CEHCs), whcih can be excreted in urine or bile.

Introduction

Vitamin E is the most potent, fat-soluble antioxidant in human plasma. Although vitamin E was first discovered in 1922, its metabolic function remains an enigma. There are eight different molecular forms with vitamin E antioxidant activity, yet the body preferentially retains the α-form of tocopherol. This preference for α-tocopherol has led the Food and Nutrition Board in its 2000 dietary reference intakes (DRIs) for vitamin E to recommend that only α-tocopherol, not the other forms, meets human requirements for vitamin E. Moreover, only α-tocopherol is recognized by the hepatic α-tocopherol transfer protein (α-TTP). This protein regulates plasma α-tocopherol concentrations. Abnormalities in the α-TTP gene lead to vitamin E deficiency in humans. Vitamin E metabolism is important for increasing excretion of excess α-tocopherol, as well as non-α-tocopherol forms of vitamin E.

General Description and Scientific Name

Dietary components with vitamin E antioxidant activity include α-, β-, γ-, and δ-tocopherols and α-, β-, γ-, and δ-tocotrienols. These compounds all have a chromanol ring with a saturate, phytyl tail (tocopherols) or an unsaturated tail (tocotrienols) and vary in the number of methyl groups on the chromanol ring. α-Tocopherol or α-tocotrienol has 3 methyl groups, β- or γ- has 2, and δ- has 1.

The naturally occurring form of α-tocopherol is called *RRR*-α-tocopherol; or on supplement labels, D-α-tocopherol; or

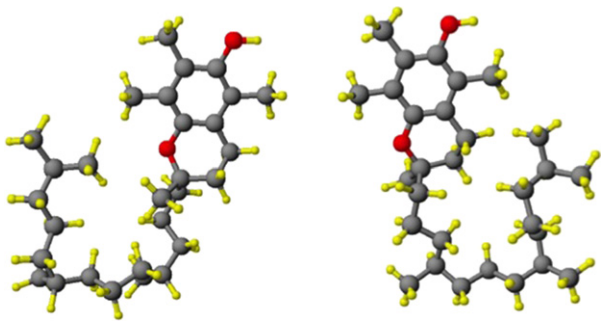

Figure 1 The naturally occurring form of a-tocopherol is called *RRR*-α-tocopherol; or more formally, 2,5,7,8-tetramethyl-2*R*-(4′*R*,8′R,12 trimethyltridecyl)-6-chromanol. Of the chiral centers at positions 2, 4′, and 8′ of α-tocopherol, position 2 is the most important for biologic activity. The *R*-conformation occurs in α-tocopherol synthesized by plants, but when α-tocopherol is chemically synthesized, the three chiral centers can each be in either the *R*- or the *S*-conformation. The α-tocopherol transfer protein prefers the 2*R*-form, not the 2*S*-form.

Table 1 Estimated average requirements (EARs), recommended dietary allowances (RDAs), and average intakes (AIs) (mg day^{-1}) for α-tocopherol – adults and children

Lifestage	*EAR*	*RDA*	*AI*
0–6 months			4
7–12 months			6
1–3 years	5	6	
4–8 years	6	7	
9–13 years	9	11	
14–18 years	12	15	
Adult (male or female)	12	15	
Pregnant	12	15	
Lactation	16	19	

Table 2 Factors to convert IU of vitamin E to mg 2*R*-α-tocopherol

	mg IU^{-1}[a]
all rac-α-Tocopherol and esters[b]	
dl-α-Tocopheryl acetate	0.45
dl-α-Tocopheryl succinate	0.45
dl-α-Tocopherol	0.45
RRR-α-Tocopherol and esters[b]	
D-α-Tocopheryl acetate	0.67
D-α-Tocopheryl succinate	0.67
D-α-Tocopherol	0.67

[a] Multiply the IU in foods or supplements times the indicated factor to obtain the mg active vitamin E.

[b] Note when the esters are synthesized the weight per IU is adjusted to include the molecular weight of the ester form. Thus, to calculate what is the mg of free tocopherol, this adjustment is not included in the calculation.

more formally, 2,5,7,8-tetramethyl-2R-(4′R,8′R,12 trimethyltridecyl)-6-chromanol (**Figure 1**). At positions 2, 4′, and 8′ of α-tocopherol are chiral carbon-centers that are in the *R*-conformation in naturally occurring α-tocopherol, but theoretically can take on either the *R*- or the *S*-conformation. Position 2 is the most important for biologic activity. Therefore, the DRIs for vitamin E are given in units of mg 2*R*-α-tocopherol (**Table 1**, see below for discussion).

The chemical synthesis of α-tocopherol results in an equal mixture of eight different stereoisomers (*RRR*, *RSR*, *RRS*, *RSS*, *SRR*, *SSR*, *SRS*, *SSS*), or more formally 2,5,7,8-tetramethyl-2*RS*-(4′*RS*,8′*RS*,12 trimethyltridecyl)-6-chromanol. To indicate that synthetic α-tocopherol is a racemic mixture, it is called *all rac*-α-tocopherol, or on supplement labels, *dl*-α-tocopherol. The first letter of the three-letter combination is the 2 position; therefore, only half of the synthetic α-tocopherol is in the active 2*R*-α-tocopherol conformation. **Table 2** lists the factors to convert IU to mg. For example, if a vitamin E supplement is labeled 400 IU and it is *dl*-α-tocopheryl acetate, then 400 times 0.45 equals 180 mg 2*R*-α-tocopherol, but if it is labeled D-α-tocopheryl acetate, then 400 times 0.67 equals 268 mg 2*R*-α-tocopherol.

Vitamin E Supplements

Most vitamin E supplements and food fortificants contain *all rac*-α-tocopherol, but can contain mixtures of tocopherols or tocotrienols. Supplements often are sold as esters, which protect α-tocopherol from oxidation. These can be acetates, succinates, or nicotinates of α-tocopherol. Either the natural stereoisomer (*RRR*-α-tocopherol) or the synthetic (*all rac*-α-tocopherol) can be sold as an ester, for example, D- or *dl*-α-tocopheryl acetate, respectively.

Dietary Vitamin E

Vitamin E can be readily obtained from food. Generally, the richest sources are vegetable oils. Wheat germ oil, safflower oil, and sunflower oil contain predominantly α-tocopherol, whereas soy and corn oils contain predominantly γ-tocopherol. All of these oils are polyunsaturated. Good sources of monounsaturated oils, such as olive or canola oils, also contain predominantly α-tocopherol. Whole grains and nuts are also good sources of vitamin E. Fruits and vegetables, although rich in water-soluble antioxidants, are not good sources of vitamin E.

α-Tocopherol Equivalents

It is often assumed for the purpose of calculating vitamin E intakes from food in α-tocopherol equivalents (α-TEs) that γ-tocopherol can substitute for α-tocopherol with an efficiency of 10%. However, functionally γ-tocopherol is not equivalent to α-tocopherol, is not coverted to α-tocopherol, and is rapidly depleted from the body. Therefore, some caution should be used in applying α-TEs to estimates of α-tocopherol intakes when corn or soybean oils (hydrogenated vegetable oils) represent the major oils present in foods. These oils have high γ-tocopherol contents and therefore the α-TEs are not reflective of only α-tocopherol, but are inflated because of the expectation that γ-tocopherol equals 10% α-tocopherol. Therefore, if food tables reporting α-TEs are used to estimate dietary α-tocopherol, α-tocopherol intakes are over-estimated. The 2000 DRIs no longer recommend use of α-TEs; only mg α-tocopherol and only 2*R*-α-tocopherol (half of the dl mg value), should be included in estimates of vitamin E intakes.

Vitamin E Actions and Metabolism

Antioxidant Activity

Vitamin E is the most potent, lipid-soluble antioxidant in human plasma and tissues. Thus, vitamin E protects polyunsaturated fatty acids within membrane phospholipids and plasma lipoproteins. When a peroxyl radical forms in a membrane, it is 1000-times more likely to attack a vitamin E molecule than a polyunsaturated fatty acid (**Figure 2**). The hydroxyl group on the chromanol ring of vitamin E reacts with the peroxyl radical to form the corresponding lipid hydroperoxide and tocopheroxyl radical. Thus, vitamin E acts as a chain-breaking antioxidant, preventing further autoxidation of lipids, but it forms a radical itself, which could re-initiate lipid peroxidation.

The tocopheroxyl radical has a number of possible fates. The tocopheroxyl radical can react with another radical to form nonreactive products. Alternatively, it can be further oxidized to the tocopheryl quinone, a two-electron oxidation

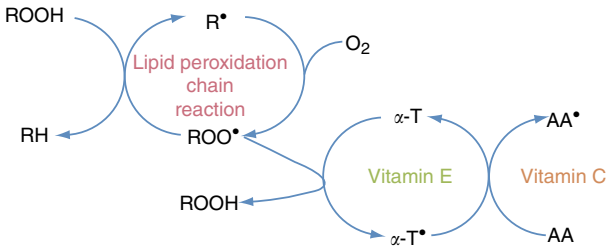

Figure 2 When a carbon-centered radical (R•) reacts with oxygen (O_2), a peroxyl radical (ROO•) is formed. The peroxyl radical is 1000-times more likely to attack a vitamin E (αT) molecule than a polyunsaturated fatty acid (RH). The hydroxyl group (OH) on the chromanol ring of vitamin E reacts with the peroxyl radical to form the corresponding lipid hydroperoxide (ROOH) and tocopheroxyl radical (α-T•). Thus, vitamin E acts as a chain-breaking antioxidant, preventing further autoxidation of lipids, but it forms a radical itself, which could re-initiate lipid peroxidation. The tocopheroxyl radical (α-T•) can react with another radical to form non-reactive products. Alternatively, it can be further oxidized to the tocopheryl quinone, a two-electron oxidation product. Another possibility is "vitamin E recycling", where the tocopheroxyl radical is restored to its unoxidized form by other antioxidants such as vitamin C or ubiquinol, or with thiols, such as glutathione. The latter possibility is the most likely one.

product. Another possibility is vitamin E recycling, where the tocopheroxyl radical is restored to its unoxidized form by other antioxidants such as vitamin C or ubiquinol, or with thiols, such as glutathione. This process will deplete these other antioxidants. For this reason, it is important to maintain a good intake of other dietary antioxidants.

Biologic Activity

Biologic activity is a term that has been used historically to indicate a disconnect between vitamin E antioxidant activities and *in vivo* activities. Observations in rodent experiments carried out in the 1930s, formed the basis for determining the biologic activity of vitamin E. Although the various vitamin E forms have somewhat similar structures and antioxidant activities, they differed in their abilities to prevent or reverse specific vitamin E deficiency symptoms (e.g., fetal resorption, muscular dystrophy, and encephalomalacia). α-Tocopherol with three methyl groups and a free hydroxyl group on the chromanol ring with the phytyl tail meeting the ring in the *R*-orientation (**Figure 1**) had the highest biological activity. This specific structural requirement for biological, but not chemical, activity is now known to be dependent on the hepatic α-TTP, as discussed in the Section on Vitamin E Bioavailability. α-TTP maintains plasma, and indirectly tissue, α-tocopherol concentrations.

Molecular Function

In addition to antioxidant activity, there have been claims that there are specific α-tocopherol-dependent functions that normalize cellular functions, are involved in cell signaling or in gene regulation. However, most of the information in this area has been obtained from *in vitro* studies. Various studies *in vivo* have not lead to clear documentation that α-tocopherol has any specific molecular function in addition to its antioxidant activity.

Vitamin E Metabolism

α- and γ-Tocopherols, as well as α- and γ-tocotrienols, are metabolized to α- and γ-carboxyethyl hydroxychroman (γ-CEHCs) (2,5,7,8-tetramethyl- and 2,7,8-trimethyl-2-(2′carboxyethyl)-6-hydroxychromans), respectively. About 1% of a dose of α-tocopherol or tocotrienol, or 5% of a dose of γ-tocopherol or tocotrienol is excreted in the urine as CEHCs. Vitamin E metabolism is a key pathway for the regulation of vitamin E status and essential for depleting the body of non-α-tocopherol forms (**Figure 3**).

Recommended Intake Levels

In 2000, the Food and Nutrition Board of the Institute of Medicine, National Academy of Sciences published the DRIs for vitamin C, vitamin E, selenium, and the carotenoids. Their recommendations for vitamin E appear in **Table 1**.

The requirements for vitamin E intakes are based primarily on long-term (5–7 years) depletion and repletion studies in humans. Serum α-tocopherol concentrations and corresponding hydrogen peroxide-induced erythrocyte hemolysis were determined at various intervals. Serum concentrations necessary to prevent *in vitro* erythrocyte hemolysis in response to known levels of vitamin E intake in subjects who had undergone experimentally-induced vitamin E deficiency were used to determine estimated average requirements (EARs) for vitamin E. The recommended dietary allowances (RDAs) are levels that represent the daily α-tocopherol intakes required to ensure adequate nutrition in 95–97.5% of the population and are an overestimation of the level needed for most people in any given group.

Vitamin E Units

According to the US Pharmacopoeia (USP), 1 international unit (IU) of vitamin E equals 1 mg *all rac* α-tocopheryl acetate, 0.67 mg *RRR*-α-tocopherol, or 0.74 mg *RRR*-α-tocopheryl acetate. These conversions were estimated on the relative biologic activities of the various forms when tested in the rat assay for vitamin E deficiency, the fetal resorption assay. IUs are currently used in labeling vitamin E supplements and food fortificants. It should be noted that the current RDA does not use vitamin E USP units but rather the recommendation for adults is set at 15 mg of *RRR*-α-tocopherol or 2*R*-α-tocopherols. Most foods contain *RRR*-α-tocopherol naturally, but foods that have been fortified with vitamin E contain the synthetic form, for example, fortified breakfast cereals. If the amount of vitamin E on the label is given in IU, then the factors given in **Table 2** must be used to multiply times the IU to obtain the mg 2*R*-α-tocopherol.

Over-Dosage

The 2000 Food and Nutrition Board of the Institute of Medicine, National Academy of Sciences recommended 1000 mg as an upper limit (UL) of all forms of α-tocopherol in supplements taken by adults 19 years and older, including pregnant and lactating women. UL were set for children and adolescents by adjusting the adult limit on the basis of relative

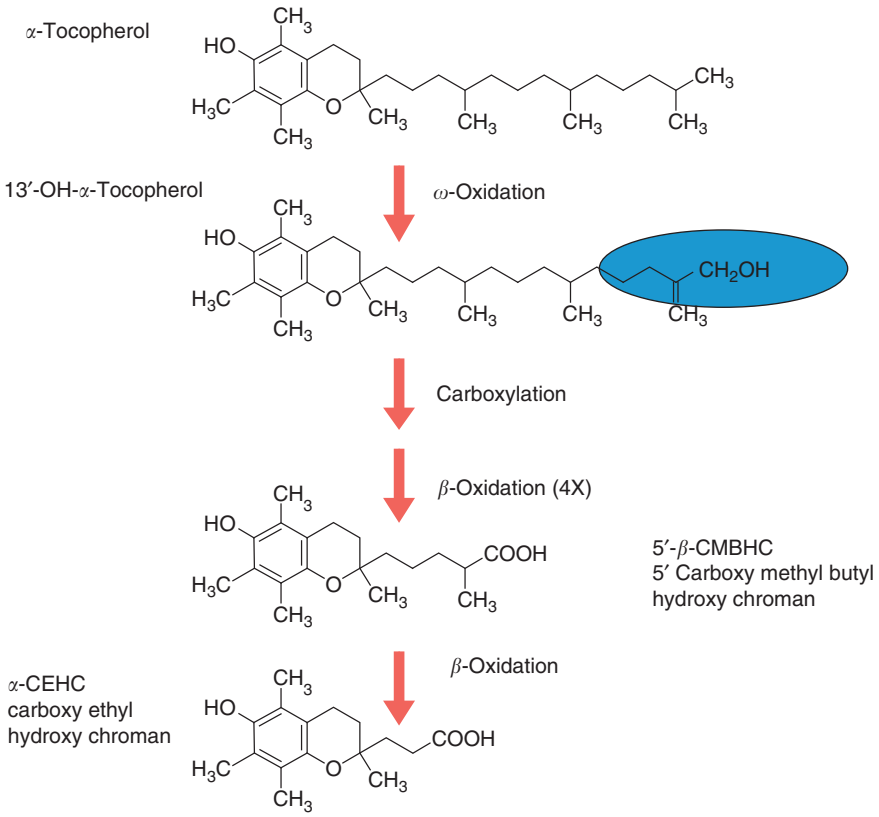

Figure 3 Shown is an example of α-tocopherol metabolism to α-CEHC. Vitamin E metabolism is a key pathway for the regulation vitamin E status and essential for depleting the body of non-α-tocopherol forms. The initial step is an ω-hydroxylation, then formation of the carboxyl group, followed by four rounds of ß-oxidation to yield the products α-CMBHC and α-CEHC, which can be excreted in the bile or the urine.

Table 3 Upper limits (UL) for α-tocopherol intakes

Age (years)	*UL (mg day^{-1})*
1–3	200
4–8	300
9–13	600
14–18	800
>19	1000

Table 4 Upper limits (UL) reported in IU for α-tocopherol-containing supplements

	Number of IU that equal the UL
all rac-α-Tocopherol and esters	
dl-α-Tocopheryl acetate	1100
dl-α-Tocopheryl succinate	1100
dl-α-Tocopherol	1100
RRR-α-Tocopherol and esters	
D-α-Tocopheryl acetate	1500
D-α-Tocopheryl succinate	1500
D-α-Tocopherol	1500

body weight. Table 3 gives the α-tocopherol UL by age group. No UL was set for infants owing to lack of adequate data. The 2000 Food and Nutrition Board did recommend that food be the only source of vitamin E for infants. However, a UL of 21 mg d^{-1} was suggested for premature infants with birth weights of 1.5 kg, based on the adult UL.

The vitamin E UL was set for supplements because it is almost impossible to consume enough α-tocopherol-containing foods to achieve a daily 1000-mg intake for prolonged periods of time. The UL was defined for all forms of α-tocopherol, not just the 2*R*-forms, because all of the forms in *all rac*-α-tocopherol are absorbed and delivered to the liver. The appropriate conversion factors are *different* from those shown in Table 2, and necessary to estimate the UL for supplements containing either *RRR*- or *all rac*-α–tocopherol supplements. The UL amounts given in IU are shown in Table 4. The UL for *RRR*-α–tocopherol is apparently higher because each capsule of *RRR*-α–tocopherol contains less α-tocopherol than does one containing *all rac*-α-tocopherol.

A number of meta-analyses of vitamin E supplementation trials have been reported. Some report increased risk of mortality with vitamin E supplementation, whereas others do not. To date, there are no mechanistic studies demonstrating how vitamin E supplements might lead to increased risk of death.

Precautions and Adverse Reactions

High vitamin E intakes are associated with an increased tendency to bleed. It is not known if this is a result of decreased platelet aggregation caused by an inhibition of protein kinase

C by α-tocopherol, some other platelet related mechanism, or decreased clotting owing to a vitamin K and E interaction causing abnormal blood clotting.

Individuals who are deficient in vitamin K or who are on anticoagulant therapy are at increased risk of uncontrolled bleeding. Patients on anticoagulant therapy should be monitored when taking vitamin E supplements to ensure adequate vitamin K intakes.

Adverse Effects of Drugs on Vitamin E Status

Drugs intended to promote weight loss by impairing fat absorption, such as Orlistat or sucrose polyester, can also impair vitamin E and other fat-soluble vitamin absorption. Therefore, multivitamin supplementation is recommended. Vitamin supplements should be taken with meals at times other than when these drugs are taken to allow adequate absorption of the fat-soluble vitamins.

Vitamin E Bioavailability

Absorption and Plasma Transport

Intestinal absorption of vitamin E is dependent upon normal processes of fat absorption. Specifically, both biliary and pancreatic secretions are necessary for solubilization of vitamin E in mixed micelles containing bile acids, fatty acids, and monoglycerides. α-Tocopheryl acetates (or other esters) from vitamin E supplements, are hydrolyzed by pancreatic esterases to α-tocopherol before absorption. Following micellar uptake by enterocytes, vitamin E is incorporated into chylomicrons and secreted into the lymph. Once in the circulation, chylomicron triglycerides are hydrolyzed by lipoprotein lipase (Figure 4). During chylomicron catabolism in the circulation, vitamin E is nonspecifically transferred both to tissues and to other circulating lipoproteins.

It is not until the vitamin E-containing chylomicrons reach the liver that discrimination between the various dietary vitamin E forms occurs (Figure 5). The hepatic α-TTP preferentially facilitates secretion of α-tocopherol, specifically *2R*-α-tocopherols, not other tocopherols or tocotrienols, from the liver into the plasma in very low-density lipoproteins (VLDLs). In the circulation, VLDLs are catabolized to low-density lipoproteins (LDL are also known as the bad cholesterol because high LDL levels are associated with increased heart disease). During this lipolytic process, all of the circulating lipoproteins become enriched with α-tocopherol.

There is no evidence that vitamin E is transported in the plasma by a specific-carrier protein, but rather is

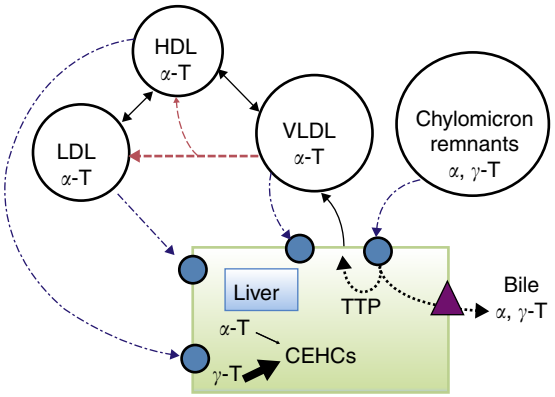

Figure 5 When the vitamin E-containing chylomicrons reach the liver, the hepatic α-TTP preferentially facilitates secretion of α-tocopherol, specifically 2*R*-α-tocopherols, not other tocopherols or tocotrienols, from the liver into the plasma. In the circulation, VLDLs are catabolized to low-density lipoproteins (LDL). During this lipolytic process, all of the circulating lipoproteins become enriched with α-tocopherol. Thus, the preference for a-tocopherol is dependent upon the hepatic secretion of α-tocopherol into plasma.

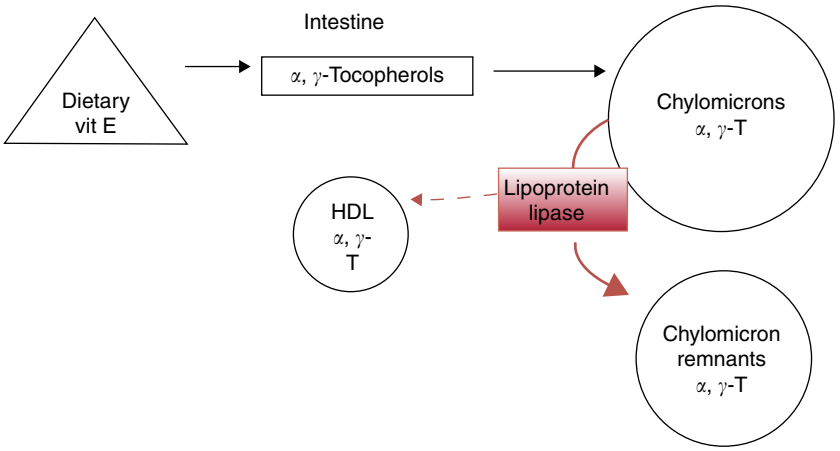

Figure 4 Dietary or supplemental vitamin E is dependent upon normal processes of fat absorption. Specifically, both biliary and pancreatic secretions are necessary for solubilization of vitamin E in mixed micelles containing bile acids, fatty acids and monoglycerides. α-Tocopheryl acetates (or other esters) from vitamin E supplements are hydrolyzed by pancreatic esterases to α-tocopherol prior to absorption. Following uptake of micelles by enterocytes, vitamin E is incorporated into chylomicrons and secreted into the lymph. Once in the circulation, chylomicron triglycerides are hydrolyzed by lipoprotein lipase. During chylomicron catabolism in the circulation, vitamin E is non-specifically transferred both to tissues and to other circulating lipoproteins, such as high-density lipoprotein (HDL).

nonspecifically transported in lipoproteins. A variety of lipoprotein receptors and lipid transporters also facilitate vitamin E disposition. An advantage of vitamin E transport in lipoproteins is that easily oxidizable lipids are protected by the simultaneous transport of this lipid-soluble antioxidant. Similarly, delivery of vitamin E to tissues is dependent upon lipid and lipoprotein metabolism. Thus, as peroxidizable lipids are taken up by tissue, the tissues simultaneously acquire a lipid-soluble antioxidant.

Plasma Concentrations, Kinetics, and Tissue Delivery

Plasma α-tocopherol concentrations in normal humans range from 11 to 37 μmol l^{-1}. When plasma lipids are taken into account the lower limits of normal are 1.6 μmol α-tocopherol per mmol lipid or 2.5 μmol α-tocopherol per mmol cholesterol. α-Tocopherol is transported in plasma lipoproteins, so if lipid concentrations are extraordinarily high or low, then correction for lipid levels are helpful to determine adequacy of vitamin E status. Additionally, α-tocopherol concentrations in erythrocytes, adipose tissue, or even peripheral nerve have been used to assess vitamin E status.

The apparent half-life of *RRR*-α-tocopherol in plasma of normal subjects is approximately 48 h, whereas those of *SRR*-α-tocopherol or γ-tocopherol are only 15 h and the tocotrienols are less than 4 h.

Vitamin E is delivered to tissues by three mechanisms: transfer from triglyceride-rich lipoproteins during lipolysis, as a result of tissue lipoprotein uptake by various receptors that mediate lipoprotein uptake, and as a result of vitamin E exchange between lipoproteins and tissues. The regulation of tissue vitamin E is not well understood, but α-tocopherol is the predominant form in tissues as a result of its dominance in plasma.

Human Vitamin E Deficiency

Vitamin E deficiency was first described in children with fat malabsorption syndromes, principally abetalipoproteinemia, cystic fibrosis, and cholestatic liver disease. Subsequently, humans with severe vitamin E deficiency with no known defect in lipid or lipoprotein metabolism were described to have a defect in the α-TTP gene. This syndrome is called ataxia with vitamin E deficiency (AVED). The demonstration of vitamin E deficiency in AVED patients solidified the role of α-TTP as a critical determinant of plasma α-tocopherol concentrations. This protein is an important factor in the discrimination between α-tocopherol and other forms of vitamin E, as well as between natural and synthetic α-tocopherols.

Erythrocyte fragility, hemolysis, and anemia were described as vitamin E deficiency symptoms in various animals fed diets devoid of vitamin E. Additionally, studies in experimental animals have shown that a deficiency of both selenium (a required component of glutathione peroxidases) and vitamin E causes a more rapid and severe onset of debilitating deficiency symptom. Deficiency of both vitamins E and C should also cause more severe antioxidant deficiency symptoms, but most animals make their own vitamin C, so this interaction has been difficult to demonstrate in animals. However, when guinea pigs were fed a vitamin E deficient diet and then made vitamin C deficient, the results were catastrophic, resulting in the animals' death within weeks of feeding the vitamin C deficient diet.

In contrast to experimental vitamin E deficiency in rodents, in humans the major vitamin E deficiency symptom is a peripheral neuropathy characterized by the degeneration of the large caliber axons in the sensory neurons.

Vitamin E deficiency occurs only rarely in humans and almost never as a result of inadequate vitamin E intakes, therefore, interactions with other nutrients have not been well studied. There have been reports of vitamin E deficiency symptoms in persons with protein–calorie malnutrition. Vitamin E deficiency does occur as a result of genetic abnormalities in α-TTP and as a result of various fat malabsorption syndromes. Vitamin E supplementation halts the progression of the neurologic abnormalities caused by inadequate nerve tissue α-tocopherol, and in some cases, has reversed them.

Patients with these disorders require daily pharmacologic vitamin E doses for life to overcome the mechanisms leading to deficiency. Generally, patients with AVED are suggested to consume 1000 mg *RRR*-α-tocopherol per day in divided doses, patients with abetalipoproteinemia 100 mg kg^{-1} body weight, cystic fibrosis 400 mg d^{-1}. However, patients with fat malabsorption owing to impaired biliary secretion generally do not absorb orally administered vitamin E. These patients are treated with special forms of vitamin E, such as α-tocopheryl polyethylene glycol succinate, that spontaneously form micelles, obviating the need for bile acids.

Chronic Disease Prevention

The frequency of human vitamin E deficiency is very rare. In individuals at risk, it is clear that vitamin E supplements should be recommended to prevent deficiency symptoms. What about vitamin E supplement use in normal individuals? Dietary changes such as decreasing fat intakes, substituting fat-free foods for fat-containing ones, and increased reliance of meals away from the home, have resulted in decreased consumption of α-tocopherol-containing foods. Therefore, intakes of the vitamin E RDA, 15 mg α-tocopherol, may be difficult. Special attention to consuming nuts, seeds, and whole grains will improve α-tocopherol intakes; alternatively multivitamin pills can be consumed.

Importantly, vitamin E's potential role in preventing or ameliorating chronic diseases associated with oxidative stress leads us to ask whether vitamin E supplements might be beneficial. For many vitamins, when excess amounts are consumed, they are excreted and provide no added benefits. Antioxidant nutrients may, however, be different. Heart disease and stroke, cancer, chronic inflammation, impaired immune function, Alzheimer's disease – a case can be made for the role of oxygen free radicals in the etiology of all of these disorders, and even in aging itself. Do antioxidant nutrients counteract the effects of free radicals and thereby ameliorate these disorders? And if so, do large antioxidant supplements have beneficial effects beyond required amounts? The 2000

DRI report on vitamin C, vitamin E, selenium, and carotenoids stated that there was insufficient proof to warrant advocating supplementation with antioxidants. But, they also stated that the hypothesis that antioxidant supplements might have beneficial effects was promising. This remains a very controversial area in vitamin E research.

One approach that has been successful in demonstrating vitamin E effectiveness in mitigating chronic disease risk is the identification of patients with increased levels of oxidative stress. One such strategy, called pharmacogenomics by its proponents, identified that diabetic patients with the haptoglobin 2–2 genotype is associated with increased risk of cardiovascular disease (CVD). These patients were found to benefit from vitamin E supplementation.

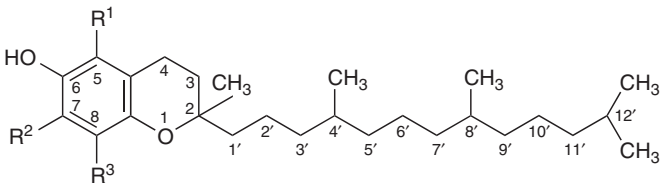
Introduction

In 1922, Evans and Bishop discovered a fat-soluble dietary constituent that was essential for the prevention of fetal death and sterility in rats accidentally fed a diet containing rancid lard. This was originally called 'factor X' and 'antisterility factor' but was later named vitamin E. Subsequently, the multiple nature of the vitamin began to appear when two compounds with vitamin E activity were isolated and characterized from wheat germ oil. These compounds were designated α- and β-tocopherol, derived from the Greek 'tokos' for childbirth, 'phorein' meaning to bring forth, and 'ol' for the alcohol portion of the molecule. Later, two additional tocopherols, γ- and δ-tocopherol, as well as four tocotrienols were isolated from edible plant oils. After the initial discovery, more than 40 years passed before it was proved that vitamin E deficiency could cause disease in humans and was associated with antioxidant functions in cellular systems. It took another 25 years before the nonantioxidant properties of the vitamin were highlighted.



The present article reviews the chemistry of the tocopherols; their dietary sources, absorption, transport, and storage; and their metabolic function. In addition, the potential role of dietary or supplemental tocopherol intake in the prevention of chronic disease and possible mechanisms for observed protective effects are discussed. Finally, a summary of the assessment of tocopherol status in humans, intake requirements, and an overview of the safety of high intakes is also provided.

Chemistry

The chemistry of vitamin E is rather complex because there are eight structurally related forms – four tocopherols (α, β, γ, and δ) and four tocotrienols (α, β, γ, and δ) – that are synthesized from homogentisic acid and isopentenyl diphosphate in the plastid envelope of plants. The structures of α-, β-, γ-, and δ-tocopherols are shown in **Figure 1**. α-Tocopherol is methylated at C5, C7, and C8 on the chromanol ring, whereas the other homologs (β, γ, and δ) have different degrees of methylation (**Figure 1**). Tocopherols have a saturated phytyl side chain attached at C2 and have three chiral centers that are in the R configuration at positions C2, C4^1, and C8^1 in the naturally occurring forms, which are given the prefix 2R, 4^1 R, and 8^1 R (designated RRR). The members of the tocotrienols are unsaturated at C3^1, C7^1, and C11^1 in the isoprenoid side chain and possess one chiral center at C2 in addition to two sites of geometric isomerism at C3^1 and C7^1. Vitamin E biological activity is expressed as milligrams of RRR-α-tocopherol equivalents (α-TEs) whenever possible. The activity of RRR-α-tocopherol is 1. The activities of RRR-β-, RRR-γ-, and RRR-δ-tocopherol are 0.5, 0.1, and 0.03, respectively.

Dietary Sources

The composition and content of the different tocopherol components in plant tissue vary considerably, ranging from

Compound	R^1	R^2	R^3
α-Tocopherol	CH_3	CH_3	CH_3
β-Tocopherol	CH_3	H	CH_3
γ-Tocopherol	H	CH_3	CH_3
δ-Tocopherol	H	H	CH_3

Figure 1 The four major forms of vitamin E (α-, β-, γ-, and δ-tocopherols) differ by the number and positions of methyl groups on the chromanol ring. In α-tocopherol, the most biologically active form, the chromanol ring is fully methylated. In β- and γ-tocopherols, the ring contains two methyl groups, whereas δ-tocopherol is methylated in one position. The corresponding tocotrienols have the same structural arrangement except for the presence of double bonds on the isoprenoid side chain of C3^1, C7^1, and C11^1.

 http://dx.doi.org/10.1016/B978-0-12-375083-9.00279-8

extremely low levels found in potato tubers to high levels found in oil seeds. α-Tocopherol is the predominant form in photosynthetic tissues and is mainly localized in plastids. The particular enrichment in the chloroplast membranes is probably related to the ability of tocopherols to quench or to scavenge reactive oxygen species (ROS) and lipid peroxy radicals by physical or chemical means. In this way, the photosynthetic apparatus can be protected from oxygen toxicity and lipid peroxidation. In nonphotosynthetic tissues, γ-tocopherol frequently predominates and can be involved in the prevention of autoxidation of polyunsaturated fatty acids (PUFAs).

Most of the tocopherol content of wheat germ, sunflower, safflower, canola, and olive oils is in the form of α-tocopherol, and these oils contain approximately 1700, 500, 350, 200, and 120 mg α-TE kg^{-1}, respectively. Vegetable oils (e.g., corn, cottonseed, palm, soybean, and sesame) and nuts (e.g., Brazil nuts, pecans, and peanuts) are rich sources of γ-tocopherol. Corn and soybean oils contain 5–10 times as much γ-tocopherol as α-tocopherol-rich sources of γ-tocopherol, and each contains approximately 200 mg α-TE kg^{-1}. Because of the widespread use of these plant products, γ-tocopherol is considered to represent ~70% of the vitamin E consumed in the typical US diet. The level of vitamin E in nuts ranges from 7 mg α-TE kg^{-1} in coconuts to 450 mg α-TE kg^{-1} in almonds. Cereals are moderate sources of vitamin E, providing between 6 (barley) and 23 mg α-TE kg^{-1} (rye). Fresh fruit and vegetables generally contain approximately 1–10 mg α-TE kg^{-1}. The concentration of vitamin E (α-tocopherol is the predominant form) in animal products is usually low, but these may be significant dietary sources because of their high consumption.

Mean dietary intakes of 6.3–13.0 mg α-TE day^{-1} have been reported in various European and the US population studies. Data from the Third National Health and Nutrition Examination Survey (1988–94) in the US indicate a median total intake (including supplements) of α-TE of 12.9 mg day^{-1} and a median intake from food only of 11.7 mg day^{-1} in men aged 31–50 years. In women in this age range, the median total intake (including supplements) of α-TE was 9.1 mg day^{-1} and the median intake from food only was 8.0 mg day^{-1}. In the US, fats and oils used in spreads, etc., contribute 20.2% of the total vitamin E intake; vegetables, 15.1%; meat, poultry, and fish, 12.6%; desserts, 9.9%; breakfast cereals, 9.3%; fruit, 5.3%; bread and grain products, 5.3%; dairy products, 4.5%; and mixed main dishes, 4.0%.

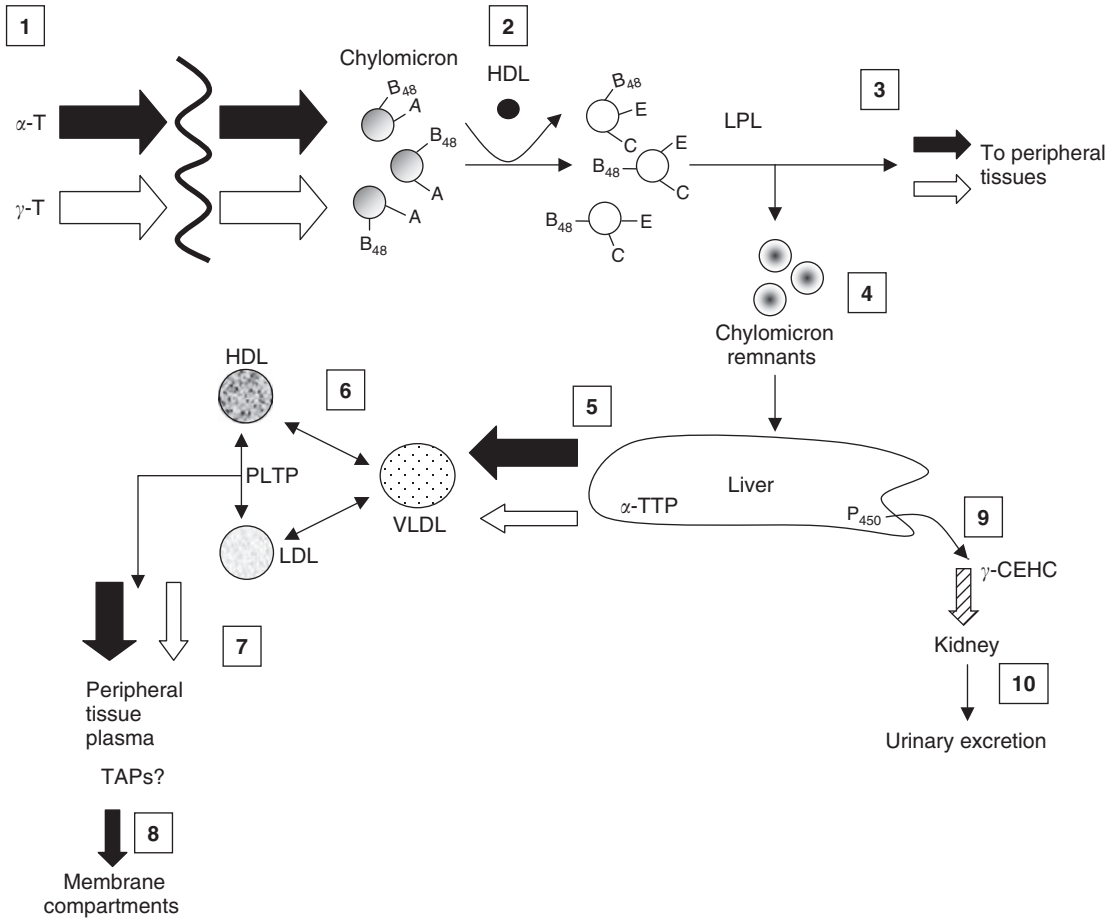
The North/South Ireland Food Consumption Survey, published in 2001, reported that the median daily intake of vitamin E from all sources was 6.3 mg in men and 6.0 mg in women aged 18–64 years. The largest contributors of vitamin E to the diet were vegetables and vegetable dishes (18.9%) and potatoes and potato products (12.4%), most likely as a result of the oils used in composite dishes. Nutritional supplements contributed 5.5% of the vitamin E intake in men and 11.9% in women overall. In the subgroup that regularly consumed nutritional supplements (23% of total), vitamin E was the nutrient most frequently obtained in supplemental form in men (78%) and women (73%). In these people, supplements made a larger contribution to total vitamin E intakes than did food.

Absorption Metabolism and Excretion

Because of its hydrophobicity, vitamin E requires special transport mechanisms in the aqueous environment of plasma, body fluids, and cells. In humans, vitamin E is taken up in the proximal part of the intestine depending on the amount of food lipids, bile, and pancreatic esterases that are present. It is emulsified together with the fat-soluble components of food. Lipolysis and emulsification of the formed lipid droplets then led to the spontaneous formation of mixed micelles, which are absorbed at the brush border membrane of the mucosa by passive diffusion. Both α- and γ-tocopherol and dietary fat are taken up without preference by the intestine and secreted in chylomicron particles together with triacylglycerol and cholesterol (**Figure 2**). The nearly identical incorporation of α- and γ-tocopherol in chylomicrons after supplementation with equal amounts of the two tocopherols indicates that their absorption is not selective (**Figure 2**). The chylomicrons are stored as secretory granula and eventually excreted by exocytosis to the lymphatic compartment, from which they reach the bloodstream via the *ductus thoracicus*. The exchange between the apolipoproteins of the chylomicrons (types AI, AII, and B_{48}) and high-density lipoprotein (HDL) (types C and E) triggers the intravascular degradation of the chylomicrons to remnants by the endothelial lipoprotein lipase (LPL) and is a prerequisite for the hepatic uptake of tocopherols (**Figure 2**). During LPL-mediated catabolism of chylomicron particles, some of the chylomicron-bound vitamin E appears to be transported and transferred to peripheral tissues, such as muscle, adipose, and brain (**Figure 2**). The formation of remnants favors the rapid uptake of the tocopherols via the hepatic receptors for apo-E and apo-B.

The chylomicron remnants are subsequently taken up by the liver, where α-tocopherol is preferentially incorporated into nascent very low-density lipoprotein (VLDL) by a specific 32-kDa α-tocopherol transfer protein (α-TTP), which enables further distribution of α-tocopherol to peripheral cells (**Figure 2**). α-TTP is mainly expressed in the liver, in some parts of the brain, in the retina, in low amounts in fibroblasts, and in the placenta. α-TTP possesses stereospecificity as well as regiospecificity toward the most abundant isomer of vitamin E, (RRR)-α-tocopherol. The sorting process does not tolerate alteration at C2. As a consequence of the selective transfer mechanism, major parts of the natural homologs and nonnatural isomers of α-tocopherol are excluded from the plasma and secreted with the bile. Relative affinities of tocopherols for α-TTP are as follows: α-tocopherol, 100; β-tocopherol, 38; γ-tocopherol, 9; and δ-tocopherol, 2. A 75-kDa plasma phospholipid transfer protein (PLTP), which is known to catalyze the exchange of phospholipids and other amphipatic compounds between lipid structures, has been shown to facilitate the exchange of α-tocopherol from VLDL to HDL and low-density lipoprotein (LDL) for further delivery to tissues (**Figure 2**).

A family of cellular tocopherol-associated proteins (TAPs) with the ability to bind and redistribute α-tocopherol has been identified. TAPs bind to α-tocopherol but not to other isomers of tocopherol. Present in all cells, TAPs may be specifically involved in intracellular α-tocopherol movement, for example, between membrane compartments and plasma



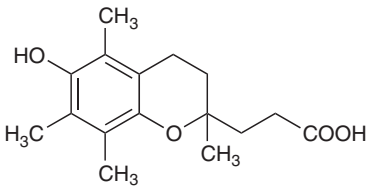


Figure 2 Absorption, transport, and metabolism of α-tocopherol (α-T) and γ-tocopherol (γ-T) in peripheral tissues. (1): Both α-T and γ-T are absorbed without preference by the intestine along with lipid and reassembled into chylomicrons. (2): Exchange between apolipoproteins of the chylomicrons (types AI, AII, and B_{48}) and HDL (types C and E) occurs. (3): Chylomicrons are degraded to remnants by LPL and some α-T and γ-T are transported to peripheral tissues. (4): The resulting chylomicron remnants are then taken up by the liver. (5): In the liver, most of the remaining α-T, but only a small fraction of γ-T, is reincorporated in nascent VLDLs by α-TTP. (6): PLTP facilitates the exchange of tocopherol between HDL and LDL for delivery to tissues. (7): Plasma tocopherols are delivered to tissues by LDL and HDL. (8): TAPs probably facilitate intracellular tocopherol transfer between membrane compartments. (9): Substantial amounts of γ-T are degraded by a cytochrome P-450-mediated reaction to 2,7,8-trimethyl-2-(β-carboxyethyl-6-hydroxychroman (γ-CEHC). (10): γ-CEHC is excreted into urine. Adapted from Azzi A and Stocker A (2000) Vitamin E: Non-antioxidant roles. *Progress in Lipid Research* 39: 231–255, and Jiang Q, Christen S, Shigenaga MK, and Ames BN (2001) γ-Tocopherol, the major form of vitamin E in the US diet, deserves more attention. *American Journal of Clinical Nutrition* 74: 714–722, with permission from American Society for Nutrition.

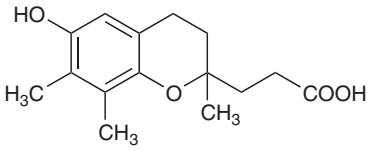

membranes, or in optimizing the α-tocopherol content of membranes.

γ-Tocopherol appears to be mainly degraded to its hydrophilic 3′-carboxychromanol metabolite, 2,7,8-trimethyl-2-(β-carboxyethyl)-6-hydroxychroman (γ-CEHC) (**Figure 3**), and excreted in the urine. The mechanism of γ-tocopherol metabolism involves terminal cytochrome P-450 (CYP)-mediated ω-hydroxylation of the tocopherol phytyl side chain, oxidation to the corresponding terminal carboxylic acid, and sequential removal of two- or three-carbon moieties by β-oxidation, ultimately yielding the hydrophilic 3′-carboxychromanol metabolite of the parent tocopherol that is excreted in the urine. Functional analysis of several recombinant human liver P-450 enzymes revealed that tocopherol ω-hydroxylase activity was associated only with the cytochrome P-450 isoform 4F2 (CYP4F2). Kinetic analysis of the tocopherol ω-hydroxylase activity in recombinant human CYP4F2 microsomal systems revealed similar K_m values (37 and 21 μM) but notably different V_{max} values (1.99 vs 0.16 nmol $nmol^{-1}$ of P-450 min^{-1}) for γ- and α-tocopherol, respectively. The data suggest a role for the CYP-mediated ω-hydroxylase pathway in the preferential physiological retention of α-tocopherol and elimination of γ-tocopherol. In nonsupplemented individuals, a substantial proportion of the estimated daily intake of γ-tocopherol is excreted in human urine as its γ-CEHC metabolite, but a much smaller proportion of α-tocopherol is excreted as 2,5,7,8-tetramethyl-2-(β-carboxyethyl)-6-hydroxychroman (α-CEHC) (**Figure 3**). α-CEHC is excreted in large amounts only when the daily intake of α-tocopherol exceeds 150 mg or plasma concentrations of α-tocopherol are above a threshold of 30–40 μmol l^{-1}. Even then, urinary excretion of α-CEHC is lower than that of γ-CEHC.

It is likely that it is the capacity of α-TTP rather than the plasma α-tocopherol concentration that determines

α-CEHC

γ-CEHC

Figure 3 Chemical structures of α-CEHC and γ-CEHC.

α-tocopherol degradation. Overall, hepatic catabolism of γ-tocopherol appears to be responsible for the relatively low preservation of γ-tocopherol in plasma and tissues, whereas α-TTP-mediated α-tocopherol transfer plays a key role in the preferential enrichment of α-tocopherol in most tissues. Supplementation with α-tocopherol depletes plasma and tissue γ-tocopherol levels. This is likely due to the preferential affinity of α-TTP for α-tocopherol. However, the depletion of γ-tocopherol may also occur because an increase in α-tocopherol may further reduce the incorporation of γ-tocopherol into VLDL, which leaves more γ-tocopherol to be degraded by CYP. However, γ-tocopherol supplementation may spare α-tocopherol from being degraded.

Plasma (RRR)-α-tocopherol incorporation is a saturable process. Plasma concentrations of α-tocopherol reach a threshold of 30–40 μmol l^{-1} despite supplementation with high levels (400 mg or greater) of (RRR)-α-tocopherol. Dose–response studies showed that the limitation in plasma α-tocopherol concentration appears to be a result of rapid replacement of circulating with newly absorbed α-tocopherol. Kinetic analysis has shown that the entire plasma pool of α-tocopherol is replaced daily. The highest concentrations of α-tocopherol in the body are in adipose tissues and adrenal glands. Adipose tissues are also a major store of the vitamin, followed by liver and skeletal muscle. The rate of uptake and turnover of α-tocopherol by different tissues varies greatly. Uptake is most rapid into lungs, liver, spleen, kidney, and red cells (in rats, $t_{1/2}<15$ days) and slowest in brain, adipose tissues, and spinal cord ($t_{1/2}<30$ days). Likewise, depletion of α-tocopherol from plasma and liver during times of dietary deficiency is rapid, whereas adipose tissue, brain, spinal cord, and neural tissues are much more difficult to deplete.

The major route for the elimination of tocopherol from the body is via the feces. Fecal tocopherol arises from incomplete absorption, secretion from mucosal cells, and biliary excretion. Excess α-tocopherol as well as forms of vitamin E not preferentially used, such as synthetic racemic isomer mixtures, or γ-tocopherol are eliminated during the process of nascent VLDL secretion in the liver and are probably excreted into bile. In addition to the urinary excretion of γ-tocopherol as γ-CEHC, biliary excretion is an alternative route for elimination of excess γ-tocopherol. This is confirmed by the fact that the ratio of γ- to α-tocopherol in bile is sevenfold higher than in plasma.

Tocopherols as Antioxidants

Under normal physiological conditions, cellular systems are incessantly challenged by stressors arising from both internal and external sources. The most important potential stressors are reduced derivatives of oxygen, which are classified as ROS, and include the superoxide anion ($O_2^{-\bullet}$), hydroxyl radical ($^{\bullet}OH$), and oxygen-centered radicals of organic compounds (peroxyl ($ROO^{\bullet}$) and alkoxyl ($RO^{\bullet}$)) together with other nonradical reactive compounds, such as hydrogen peroxide (H_2O_2). In addition, reactive nitrogen species such as nitric oxide ($NO^{\bullet}$), nitrogen dioxide ($NO_2^{\bullet}$), peroxynitrite ($ONOO^-$), and hypochlorous acid are involved.

Cellular systems have evolved as a powerful and complex antioxidant defense system to limit inappropriate exposure to these stressors. α-Tocopherol is quantitatively the most important chain-breaking antioxidant in plasma and biological membranes. The antioxidant activities of chain-breaking antioxidants are determined primarily by how rapidly they scavenge peroxyl radicals, thereby preventing the propagation of free radical reactions. When the chromanol phenolic group of α-tocopherol (TOH) encounters a $ROO^{\bullet}$ it forms hydroperoxide (ROOH), and in the process a tocopheroxyl radical ($TO^{\bullet}$) is formed:

$$TOH + ROO^{\bullet} \xrightarrow{k_1} ROOH + TO^{\bullet}$$

The rate constant (k_1) for hydrogen abstraction from α-tocopherol is 2.35×10^6 M^{-1} s^{-1}, which is higher than that for the other tocopherols and related phenols. Because the rate constant (k_2) for the chain propagation reaction between $ROO^{\bullet}$ and an unsaturated fatty acid (RH) ($ROO^{\bullet} + RH \rightarrow ROOH$) is much lower than k_1, at approximately 10^2 M^{-1} s^{-1} α-tocopherol outcompetes the propagation reaction and scavenges the $ROO^{\bullet}$ $\sim 10^4$ times faster than RH reacts with $ROO^{\bullet}$. Thus, the kinetic properties of antioxidants, in particular α-tocopherol, require that only relatively small concentrations are required for them to be effective. The concentration of α-tocopherol in biological membranes is approximately 1 mol per 1000–2000 mol phospholipids (i.e., $\sim 1{:}10^3$). Ascorbic acid can reduce the tocopheroxyl radical ($TO^{\bullet}$) to its native state, and it has been concluded that part of the reason why low concentrations of α-tocopherol are such efficient antioxidants in biological systems is because of this capacity to be regenerated by intracellular reductants such as ascorbic acid.

The heterocyclic chromanol ring of α-tocopherol has an optimized structure for resonance stabilization of the unpaired electron of the α-tocopheroxyl radical, and the electron-donating substituents (e.g., the three methyl groups) increase this effect. Because γ-tocopherol lacks one of the electron-donating methyl groups on the chromanol ring, it is somewhat less potent in donating electrons than α-tocopherol and is thus a slightly less powerful antioxidant. However, the

unsubstituted C5 position on γ-tocopherol allows it to trap lipophilic electrophiles such as peroxynitrite, thereby protecting macromolecules from oxidation.

Vitamin E Deficiency

Vitamin E deficiency is seen rarely in humans. However, there may be a risk of vitamin E deficiency in premature infants because the placenta does not transfer α-tocopherol to the fetus in adequate amounts. When it occurs in older children and adults, it is usually a result of lipoprotein deficiencies or a lipid malabsorption syndrome. These include patients with abetalipoproteinemia or homozygous hypobetalipoproteinemia, those with cholestatic disease, and patients receiving total parenteral nutrition. There is also an extremely rare disorder in which primary vitamin E deficiency occurs in the absence of lipid malabsorption. This disorder is a rare autosomal recessive neurodegenerative disease caused by mutations in the gene for α-TTP. This disorder is known as ataxia with vitamin E deficiency (AVED). Patients with AVED have extraordinary low plasma vitamin E concentrations ($<5\ \mu g\ ml^{-1}$) and have an onset between 4 and 18 years, with progressive development of peripheral neuropathy, spinocerebellar ataxia, dysarthria, the absence of deep tendon reflexes, and vibratory and proprioceptive sensory loss. Patients with an α-TTP defect have enhanced urinary excretion of α-CEHC despite having much lower plasma α-tocopherol concentrations than healthy subjects. Therapeutic and prophylactic vitamin E supplementation (up to 2000 mg day^{-1}) prevents the onset of the disease before irreversible neurological damage develops.

Tocopherols and Low-Density Lipoprotein Modification

The hypothesis that oxidative stress plays an important role in the pathogenesis of atherosclerosis is generally accepted. Substantial *in vitro* evidence indicates that oxidized LDL is the component central to the initiation and/or progression of atherogenesis at the molecular and cellular level. The typical LDL particle is not only rich in cholesterol, but also contains approximately 1300 molecules of RH, which are very sensitive to oxidation. Vitamin E, mainly α-tocopherol, is quantitatively the most important lipophilic antioxidant present in LDL particles. On average, each LDL particle is protected by ~6 mol α-tocopherol (range, 3–15 mol), 1 mol of γ-tocopherol, and small amounts of carotenoids.

All major cells of the artery wall, such as monocyte macrophages, endothelial cells, and smooth muscle cells, can modify LDL oxidatively *in vitro*. Monocytes have been shown to induce peroxidation of lipids such as those in LDL by the generation of reactive species, including superoxide anion, hydrogen peroxide, and hydroxyl radicals. Other oxidants have been implicated, including 15-lipoxygenase, myeloperoxidase-generated hypochlorous acid, and reactive nitrogen species such as peroxynitrite. *In vivo*, oxidized LDL particles are recognized by macrophage scavenger receptors and taken up by macrophages, forming lipid-laden foam cells in the fatty streak lesions. The free radical oxidation of LDL results in numerous structural changes that all depend on a common event – the peroxidation of PUFAs in the LDL particle.

In vitro studies have indicated that increasing the vitamin E content of LDL particles increases their resistance to oxidation and decreases their uptake by macrophages. Vitamin E supplementation has also been reported to suppress macrophage uptake of oxidized LDL in human arterial lesions and decrease urinary F_2-isoprostane (a 'footprint' of free radical-mediated oxidation of arachidonic acid) concentrations. Reactive nitrogen species are also implicated in aortic oxidation of LDL and therefore potentially in atherosclerosis. Because of the nonsubstituted 5-position, γ-tocopherol reacts with peroxynitrite and other electrophilic mutagens generated during inflammation and forms a stable carbon-centered adduct, 5-nitro-γ-tocopherol. This mechanism of protecting LDL may be significant when γ-tocopherol constitutes a major portion of vitamin E in the diet. It is worth noting that the ability of γ-tocopherol to attenuate oxidative damage produced by these reactive species may prevent or delay the progression of other diseases as well as cardiovascular disease (CVD), in which inflammation plays a role, such as cancer, rheumatoid arthritis, inflammatory bowel disease, and neurodegenative disorders. In addition, γ-CEHC has natriuretic activity and functions in the kidney to control sodium excretion, and it regulates the body's extracellular fluid volume, an important determinant in hypertension and congestive heart failure.

Tocopherols and Other Metabolic Functions

Vitamin E, in addition to having a protective role in the oxidative modification of LDL, may affect or limit the progression of atherosclerosis and a number of other conditions in ways that are unrelated to its antioxidant activity. Some of these effects appear to stem from the ability of α-tocopherol, at physiological concentrations of vitamin E, to activate protein phosphatase 2 A, which inhibits the activity of protein kinase C (PKC), a biological indicator of inflammation, by dephosphorylating the protein. PKC is an important element in the signal transduction cascade mediated by growth factors, such as platelet-derived growth factors, which are necessary for the progression and completion of the cell proliferation cycle.

The cellular effects of α-tocopherol-mediated inhibition of PKC depend on the cell type in question, but the cumulative effect is highly protective against the progression of atherosclerosis. PKC inhibition results in reduced smooth muscle cell proliferation, inhibition of platelet aggregation, and thus delayed intra-arterial thrombus formation. Endothelial cell function is preserved by the downregulation of adhesion molecule (ICAM-1 and VCAM-1) expression (possibly by downregulation of nuclear factor-κB) and hence prevention of monocyte and neutrophil adhesion, which is an important early event in the initiation of fatty streak formation and atherogenesis. In addition, PKC inhibition in monocytes reduces the production of ROS by impairment of NADPH-oxidase assembly, which may help to reduce LDL oxidation.

The release of proinflammatory cytokines in monocytes, such as interleukin-1β and tumor necrosis factor-α, is impeded by α-tocopherol-mediated inhibition of the 5-lipoxygenase pathway, and production of eicosanoids, such as

prostaglandin E_2 and thromboxane A_2, is impeded by γ-tocopherol-mediated inhibition of the cyclooxygenase pathway. Lower circulating levels of inflammatory mediators, which are aggregatory and vasoconstrictive, as well as inhibition of monocyte chemoattractant protein-1 (MCP-1) production, reduces the attraction of monocytes to inflammatory sites at the arterial wall and prevents the formation of foam cells. Furthermore, α-tocopherol increases production of prostacyclin, which has antiaggregatory and vasodilatory properties, thereby reducing the risk of a coronary event. There is evidence that in a formed atherosclerotic plaque, vitamin E may have a stabilizing effect and prevent its rupture and subsequent clot formation. This may be an important contributor to the prevention of heart disease because plaque types that are most subject to rupture present the greatest threat.

Nitric oxide (NO) produced by NO synthase in the endothelium is important in the maintenance of vascular tone; it suppresses the expression of proinflammatory cytokines, adhesion molecules, and MCP-1. It also inhibits platelet adhesion, maintains the integrity of the arterial wall, and acts as an antioxidant. Vitamin E can reduce the inhibition of NO synthase by ROS, thus maintaining NO production, either through its antioxidant activity or perhaps by suppressing PKC activity in smooth muscle.

Tocopherols and Cardiovascular Disease – Epidemiological Evidence

The effects of dietary vitamin E have been examined in several studies, many of which have reported a clear association between the reduction in the relative risk of CVD and high intake or supplement of vitamin E, although some have shown no such association. The vitamin substudy of the WHO/MONICA Project showed that in European populations whose classical risk factors for CVD were very similar, the sevenfold differences in CVD mortality could be explained at least to approximately 60% by differences in the plasma levels of vitamin E and up to 90% by the combination of vitamins E, A, and C. The Edinburgh Case Control Study and Basel Prospective Study consistently revealed an increased risk of ischemic heart disease and stroke for low plasma levels of vitamin E. However, other European population studies have not found an association between blood levels of vitamin E and end points of CVD. In the EURAMIC study, the adipose levels of vitamin E did not correlate with the relative risk of myocardial infarction.

A number of prospective studies have examined the association between vitamin E intake and risk of coronary heart disease (CHD). The Nurses' Health Study, conducted on 87 245 women, showed a 34% reduction in CHD in women who had consumed vitamin E supplements containing more than 67 mg α-TE daily for more than 2 years. However, there was no significant effect of vitamin E obtained from food sources. The Established Populations for Epidemiolodic Studies of the Elderly trials showed that the use of vitamin E supplements significantly decreased risks for all-cause-mortality and mortality from heart disease. Another prospective study, performed in Canada, reported a consistent inverse association between CVD and vitamin E supplement usage. The Health Professionals Study, conducted on 39 910 men aged 40–75 years, also showed that dietary intakes of vitamin E were not significantly correlated with reduced risk of CHD or death. A protective effect was seen in those who took 67–160 mg supplemental α-TE daily for more than 2 years. In contrast, the Iowa Women's Health Study reported that dietary vitamin E (mainly γ-tocopherol) was inversely associated with the risk of death from CVD. This association was particularly striking in the subgroup of women who did not consume vitamin supplements. There was little evidence that the intake of vitamin E from supplements (mainly α-tocopherol) was associated with a decreased risk of death from CVD. The reasons for the differences between dietary and supplemental vitamin E are not clear. However, some epidemiological studies point to the potential importance of γ-tocopherol in preventing heart disease. High dietary intake of nuts, an excellent source of γ-tocopherol, lowered serum cholesterol, improved plasma lipid profiles, and was inversely associated with the risk of death from heart disease.

The ability of α-tocopherol supplementation to prevent cardiovascular events in different populations was tested in four larger prospective clinical trials: the α-Tocopherol, β-Carotene Cancer Prevention (ATBC) study, the Cambridge Heart Antioxidant Study (CHAOS), the Gruppo Italiano per lo studio della Sopravvivenza nell'Infarto Miocardito (GISSI) trial, and the Heart Outcome Prevention Evaluation (HOPE) study. In addition, at least two smaller prospective clinical trials have been completed: the Secondary Prevention with Antioxidants of Cardiovascular Disease in Endstage Renal Disease (SPACE) study and the Antioxidant Supplementation in Atherosclerosis Prevention Study (ASAP).

In the ATBC study, the subjects who were supplemented with 50 mg all rac-α-tocopheryl acetate day^{-1} for 5–8 years had only a moderately lower incidence (4%) of angina pectoris than did the control subjects, and among male smokers, cardiovascular mortality did not differ significantly between those who received supplementation and those who did not. However, subjects who received supplementation had a significantly higher incidence of hemorrhagic stroke than did the control subjects. Note that the ATBC study was not designed to investigate CVD development. The results of the CHAOS trial, the first prospective trial with CVD as an end point, were encouraging. The risks of nonfatal myocardial infarction declined 77% and total (fatal plus nonfatal) myocardial infarction declined 47% when patients with established coronary artery disease were treated with 268 or 536 – mg α-TE daily for approximately 500 days. The GISSI study showed that feeding 211 mg α-TE day^{-1} for 3.5 years did not significantly reduce the rate of all-cause death, nonfatal myocardial infarction, or nonfatal stroke. However, in a later four-way reanalysis in which each individual variable was considered as an end point, there were significantly fewer (20%) cardiovascular deaths in the α-tocopherol group than in the control group. The HOPE study reported that vitamin E (400 IU (268 mg) day^{-1} RRR-α-tocopherol) treatment of CVD patients had no effect on reducing the primary end points, which included nonfatal myocardial infarction, stroke, and cardiovascular death. In the SPACE trial, hemodialysis patients with preexisting CVD received 536 mg (RRR)-α-tocopherol or placebo day^{-1}. Patients

who received vitamin E had a striking 54% reduction in cardiac events compared with control subjects.

In the ASAP study, men and women (all subjects had hypercholesterolemia at entry) were given vitamin E (91 mg twice daily), slow-release vitamin C (250 mg twice daily), a combination of both, or placebo for 3 years. The progression of atherosclerosis (the mean intima-media thickness of the common carotid artery measured) was significantly retarded only in the men who smoked and took both vitamins. It is important to note that, in general, women develop fewer cardiovascular events than do men. Thus, women may profit less from vitamin E treatment than men. In studies in which many women are enrolled, the low incidence of CVD may weaken the statistical power of the overall trial.

Tocopherols and Cancer – Epidemiological Evidence

Clinical and epidemiological data, together with evidence from experimental models, support a role for the involvement of free radicals throughout the cancer process. Attempts to prevent cancer using vitamin E are based on the rationale that oncogenesis results from free radicals attacking DNA. As an antioxidant, vitamin E may inhibit cancer formation by scavenging ROS or reactive nitrogen species. Several studies of oral, pharyngeal, and cervical cancer found a relationship between vitamin E status and cancer risk. The evidence for stomach and pancreatic cancers has not been consistent, and no association with breast cancer has been found.

The Linxian, China, intervention trial provided evidence that nutritional supplementation may lower the risk of certain cancers. A modest but significant reduction in cancer mortality was observed in a general population trial in those receiving daily (for 5.25 years) a combination of β-carotene (15 mg), vitamin E (30 mg), and selenium (50 μg). The subjects who received this mixture had a 13% lower incidence of cancer and a 10% lower mortality from stomach and esophageal cancer than did the subjects who did not receive the mixture. In the ATBC study, male smokers who took vitamin E supplements had a 34% lower incidence of prostate cancer and 41% lower mortality from prostate cancer than did those who did not take the supplements. In the US, in a nested case-control study conducted to examine the association of α-tocopherol, γ-tocopherol, and selenium with the incidence of prostate cancer, a striking fivefold reduction in risk was observed for the men in the highest quintile of γ-tocopherol compared with those in the lowest. Overall, evidence for the protection from cancer by vitamin E is not compelling.

Tocopherols and Other Diseases – Epidemiological Evidence

Vitamin E appears to act as an immunosuppressant due to its ability to suppress both humoral and cellular immune responses. Tocopherol supplementation significantly enhances lymphocyte proliferation, interleukin-2 production, and delayed-type hypersensitivity skin response and decreases prostaglandin E_2 production by inhibiting cyclooxygenase activity. There appears to be compelling evidence that intervention with dietary antioxidants, such as vitamin E, may help maintain the well-preserved immune function of 'very healthy' elderly, restore the age-related decrease in immune function, and reduce the risk of several age-associated chronic diseases. Epidemiological evidence suggests an association between the incidence of cataract and vitamin E status. In a prospective study, the sum of serum α- and γ-tocopherol, but neither tocopherol alone, was inversely associated with the incidence of age-related nuclear cataracts.

Among the most common neurologic diseases are neurodegenerative disorders such as Alzheimer's and Parkinson's disease, which may be caused by oxidative stress and mitochondrial dysfunction leading to progressive neural death. An increasing number of studies show that antioxidants (vitamin E and polyphenols) can block neuronal death *in vitro*. In a 2-year, double-blind, placebo-controlled, randomized trial of patients with moderately severe impairment from Alzheimer's disease, treatment with 1340 mg day^{-1} α-TE significantly slowed the progression of the disease. Clinical treatment of Alzheimer's patients with large doses of vitamin E (670 mg α-TE twice daily) is one of the key therapeutic guidelines of the American Academy of Neurology. In a multicentre, double-blind trial, vitamin E (1340 mg α-TE day^{-1}) was not beneficial in slowing functional decline or ameliorating the clinical features of Parkinson's disease. Administration of vitamin E significantly relieved symptoms in patients suffering from several types of acute or chronic inflammatory conditions, such as acute arthritis, rheumatoid arthritis, and osteoarthritis.

Vitamin E Status and Requirements

Interest in the role of vitamin E in disease prevention has encouraged the search for reliable indices of vitamin E status. Most studies in human subjects make use of static biomarkers of status, usually α-tocopherol concentrations in plasma, serum, erythrocytes, lymphocytes, platelets, lipoproteins, adipose tissues, buccal mucosal cells, LDL, and the α-tocopherol: γ-tocopherol ratio in serum or plasma. Other markers of vitamin E status include susceptibility of erythrocyte or plasma LDL to oxidation, breath hydrocarbon exhalation, and the concentration 16.2 μmol^{-1} are normally regarded as indicating a deficient, low, and acceptable vitamin E status, respectively. It is recommended that plasma or serum α-tocopherol concentrations be lipid-corrected (i.e., expressed relative to either the sum of cholesterol and triacylglycerol or cholesterol alone). For convenience, α-tocopherol:cholesterol is the simplest to obtain and probably the most useful, with values below 2.2 μmol α-tocopherol $mmol^{-1}$ cholesterol indicating a risk or deficiency and an optimal 5.2. It has been estimated that an average daily dietary intake of 15–30 mg α-tocopherol would be required to maintain this plasma level, an amount that could be obtained from dietary sources if a concerted effort were made to eat foods rich in vitamin E.

The US Institute of Medicine Food and Nutrition Board set an estimated average requirement (EAR) of 12 mg α-tocopherol for adults > 19 years on the criterion of vitamin E intakes that were sufficient to prevent hydrogen peroxide-induced hemolysis in men. The same value was set for men and women on the basis that although body weight is smaller

on average in women than men, fat mass as a percentage of body weight is higher on average in women. Because information is not available on the standard deviation of the requirement for vitamin E, the recommended dietary allowance was established for men and women as the EAR (12 mg) plus twice the coefficient of variation (assumed to be 10%), rounded up, giving a value of 15 mg day^{-1}. In Europe, the Scientific Committee for Food did not set a population reference intake (PRI) for vitamin E on the basis that there is no evidence for deficiency from low intakes, and the frequency of distribution of intakes is skewed to the right, making it difficult to set a PRI that is not inappropriately high, especially for those with a low consumption of PUFA, whose requirements are lower than those with a high consumption of PUFA.

It has been suggested that the optimum concentration of α-tocopherol in plasma for protection against CVD and cancer is >30 μmol l^{-1}, given normal plasma lipid levels and in conjunction with a plasma vitamin C concentration >50 μmol l^{-1} and a β-carotene level >0.4 μmol l^{-1}. This has not been proven in large-scale human intervention trials, but even in the absence of conclusive evidence for a prophylactic effect of vitamin E on chronic disease prevention, some experts believe that a recommendation of a daily intake of 87–100 mg α-tocopherol is justifiable based on current evidence. Realistically, these levels can be achieved only by using nutritional supplements. The tolerable upper intake level for vitamin E is 1000 mg day^{-1}, based on studies showing hemorrhagic toxicity in rats, in the absence of human dose–response data.

VITAMIN K

X Fu and SL Booth, USDA Human Nutrition Research Center on Aging at Tufts University, Boston, MA, USA

© 2013 Elsevier Ltd. All rights reserved.

Introduction

The discovery of vitamin K as an essential nutrient arose in the late 1920s from Henrik Dam's studies of sterol metabolism. He observed that chicks fed with a fat-free diet developed subcutaneous hemorrhages and anemia. A lipid extract of liver or of certain plant tissues was curative, and by 1935 he claimed the discovery of a new vitamin in these extracts that he named 'vitamin K' from the German word 'Koagulation.' By the late 1930s, two chemically similar forms of the vitamins from different sources were recognized, namely phylloquinone or K_1 and menaquinones or K_2, which had been isolated from alfalfa and from putrefied fish meal, respectively (**Figure 1**). Phylloquinone, with its saturated phytyl side chain, is found in plant tissues, especially in green leafy ones, where it acts as a component of the electron transport chain. The menaquinones, or MK-n, by contrast, comprise a broad family of representatives that have a variable length, unsaturated side chain, and are composed of one or more (sequential) isoprene units in place of the saturated phytyl side chain. These menaquinones can be produced by certain types of bacteria, both in the large bowel of animals and at other locations where they may contribute to human food sources of menaquinones. The specific menaquinone with the same side chain length as phylloquinone is called menaquinone-4 (MK-4), or menatetranone, which is produced commercially as human medication, especially in Japan. Menadione, a water-soluble form of the vitamin that has a single methyl group in place of the side chain, can be converted to MK-4 *in vivo*, and is used in animal feeds, but it is not used in humans because of its toxicity at high doses. Phylloquinone is converted to MK-4 through synthesis within the tissue, or by transport to the tissue through circulation. Menadione is the intermediate vitamin K metabolite in this conversion. There is an evidence that UbiA prenyltransferase domain-containing protein1 (UBIAD1) is a key enzyme for MK-4 biosynthesis, and possesses side chain cleavage and prenylation activities. Most bacterially synthesized menaquinones have longer side chains, typically 7–9 isoprene units and up to 13, which are indicated by '*n*' in the MK-*n* shorthand notation.

Food Sources, Absorption, and Catabolism

Food sources of phylloquinone (**Table 1**) include green leafy vegetables as the major quantitative source. The longer-chain menaquinones, MK 7–9, are typically obtained from foods, such as cheeses or Japanese 'natto' (fermented bean curd), in which bacterial fermentation has occurred. Smaller amounts of both phylloquinone and menaquinones are obtained from liver and other animal-derived foods. Phylloquinone-rich plant oils when hydrogenated form 2′,3′-dihydrophylloquinone, which differs from the parent form by saturation of the 2′,3′ double bond on the side chain. Dihydrophylloquinone is most prevalent in margarines, prepared foods, and infant formulas. With a general trend toward a reduction in the USA in hydrogenation of plants oils, it is expected that there will be an overall reduction in dihydrophylloquinone in the USA food supply.

Phylloquinone is highly lipophilic; however, at low concentrations it is transported by a saturable, energy-dependent transport system across the gut wall, mainly in the upper small intestine. Phylloquinone in foods consisting of plant tissues is much less readily bioavailable for absorption than the pure

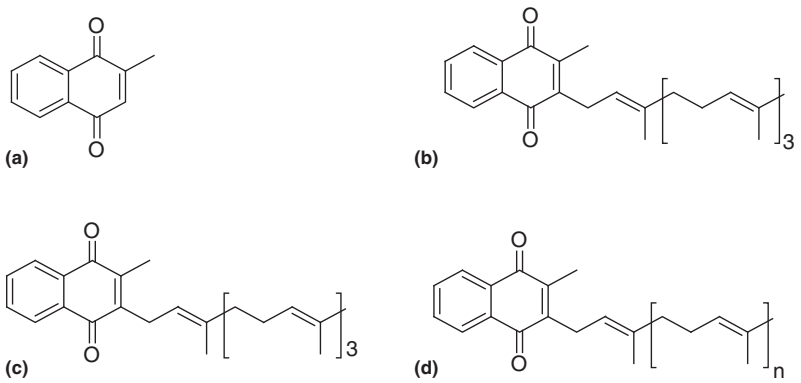

Figure 1 Chemical structures of: (a) menadione, (b) phylloquinone, (c) MK-4, and (d) menaquinones, where n represents the number of repeating isoprene units.

Table 1 Phylloquinone concentrations (μg per measure) in common foods[a]

Food Item	*Common measure*	*Content*[b]
Vegetables		
Collards, frozen, cooked	1 Cup	1059
Spinach, cooked	1 Cup	888
Brussels sprouts, cooked	1 Cup	300
Corn, sweet, cooked	1 Ear	97.2
Broccoli, raw	1 Cup	89.4
Cucumbers, raw	1 Large	49.4
Celery, raw	1 Cup	35.2
Lettuce, green leaf, raw	1 Cup	35
Asparagus, boiled	4 Spears	30.4
Carrots, raw	1 Cup	14.5
Protein sources		
Soybeans, mature cooked	1 Cup	33
Egg, whole, cooked	1 Large	2.6
Beef, cooked	3 oz	1.9
Milk, whole, 3.25% fat	1 Cup	0.5
Fish, salmon, smoked	3 oz	0.1
Prepared foods		
Pizza, cheese	1 Serving	4.2
Apple pie	1 Piece	4.1
Salad dressings	1 Tbsp	2.2
Potato chips	1 oz	2.0
Cheese, cheddar	1 oz	0.8
Fats and oils		
Margarine, regular	1 Tbsp	13.2
Olive oil, cooking	1 Tbsp	8.1
Soybean oil, cooking	1 Tbsp	3.4
Butter, salted	1 Tbsp	1.0
Fruits		
Blackberries, raw	1 Cup	28.5
Apples, with skin	1 Apple	3.0
Pineapple, raw	1 Cup	1.1
Bananas, raw	1 Banana	0.6
Strawberries, raw	1 Strawberry	0.3

[a]USA Department of Agriculture's National Nutritional Database for Standard Reference, Release 22 (http://www.nal.usda.gov/fnic/foodcomp).
[b]The unit is μg phylloquinone per measure.

vitamin since it is tightly bound to the thylakoid membranes of the chloroplasts, and the absorption of vitamin K from plant foods is considerably improved by including additional fat in the meal. Its absorption also depends on the stimulation of bile salt and pancreatic lipase secretions. The long-chain menaquinones, which are even more lipophilic, are only passively absorbed and are much less bioavailable for absorption than phylloquinone. Current understanding of the relative bioavailability and bioactivity of the different forms and food sources of vitamin K is limited and needs more research.

The triglyceride-rich lipoproteins (TRL) are the major carriers of phylloquinone in the circulation, with lesser but significant amounts carried by low- and high-density lipoproteins (LDL and HDL). Long-chain menaquinones are mainly transported by LDL. Plasma vitamin K concentrations, which are typically in the low nanomolar range in humans are much lower than for the other fat-soluble vitamins (A, D, and E), and they are strongly correlated with the triglyceride content of the plasma. Based on early isotopic work in humans, the turnover of phylloquinone results in *ca*. 40–50% of the exchangeable body pool being transferred via the bile into the feces and 20% being excreted into the urine, the latter including the excretion of oxidized products that become conjugated as glucuronides. Through the use of ^{13}C-labeled vegetables, it has been determined that phylloquinone has a plasma half-life of 8.8 h, and a tissue half-time of 215 h. No comparable studies using stable isotopes have been reported for any of the menaquinones.

Human urinary metabolites of phylloquinone comprise of glucuronide conjugates of carboxylic aglycone moieties, including two side chain-shortened carboxylic acids. These metabolites respond to dietary manipulation of phylloquinone and 2′,3′-dihydrophylloquinone, which suggests utility as biological markers of vitamin K dietary exposure and status.

The enzymatic pathway for the catabolism of vitamin K has not been studied in detail. Vitamin K upregulates CYP3A isoforms by binding to and activating the steroid and xenobiotic receptor (SXR), also known as the pregnane X receptor (PXR). The SXR is a nuclear receptor which acts as a sensor for the presence of many drugs such as phenobarbital, taxol, rifampicin, and others, and initiates the detoxification process. SXR is involved in the transcriptional regulation of enzymes, such as cytochrome P-450s, which through transporter molecules clear these substances from the body.

Vitamin K-Dependent (VKD) Proteins

Vitamin K acts as the essential recycling cofactor (or cosubstrate) for all vitamin K-dependent protein carboxylation and Gla-forming reactions (**Figure 2**). In its dihydro or quinol form, the vitamin reacts with molecular oxygen, thereby creating a highly reactive, high-energy carbanion at the glutamate (Glu) site for insertion of carbon dioxide, creating a new Gla residue. This vitamin K quinol oxidation step provides the essential energy for the endothermic carboxylation step. The other product of the reaction is the vitamin K epoxide, comprising a three-membered carbon–oxygen ring. Since the oxidized vitamin needs to be recycled back to the quinol form before the next protein carboxylation cycle, a two-stage reduction process ensues, forming first vitamin K quinone and then the original quinol (**Figure 2**). Both of these reduction steps can be catalyzed by the enzyme vitamin K epoxide reductase, which is linked to a dithiol–disulfide reducing couple and which is highly sensitive to inhibition by the coumarin class of drugs, of which warfarin is the best known and most commonly used. The reduction of the intermediate vitamin K quinone to its quinol form can also be catalyzed by another, NAD(P)H-dependent, quinone reductase that is warfarin resistant, and for this reason the inhibition of carboxylation by warfarin can be reversed or antagonized by large doses of vitamin K provided exogenously in its normal quinone form.

The VKD coagulation proteins, factors II, VII, IX, and X, and proteins C, S, and Z, are synthesized in the liver.

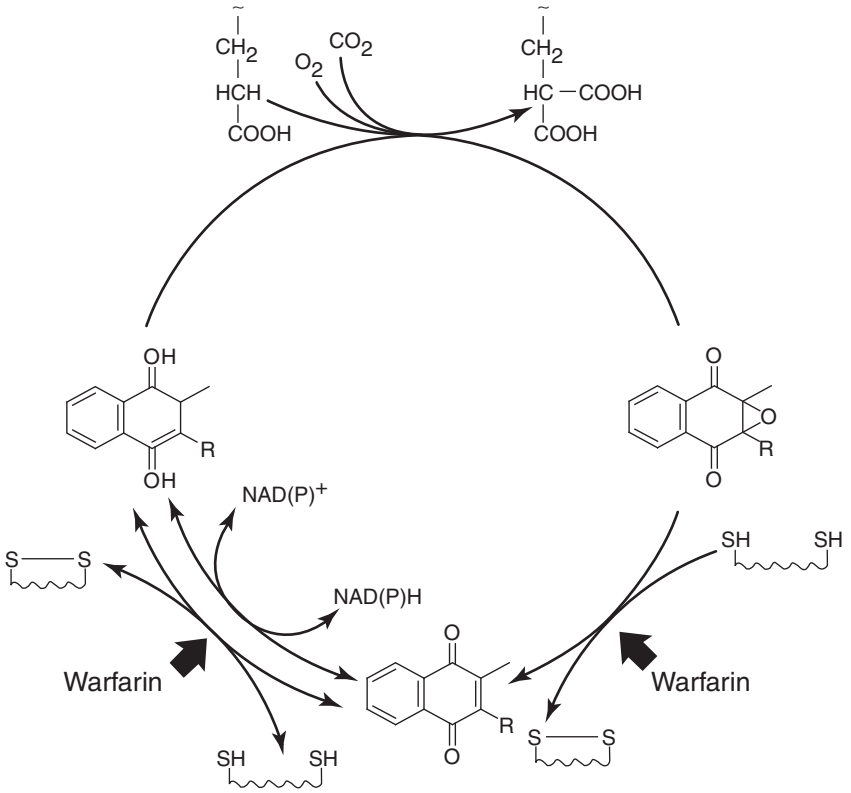

Figure 2 Tissue recycling of vitamin K. Vitamin K epoxide formed in the carboxylation reaction is reduced to the quinine form of the vitamin by a warfarin-sensitive enzyme – the vitamin K epoxide reductase. This reaction is driven by a reduced dithiol. The naphthoquinone form of the vitamin can be reduced either by the same warfarin-sensitive dithiol-driven reductase or by one or more of the hepatic NADH or NADPH-linked quinone reductases that are less sensitive to warfarin.

The extrahepatic VKD proteins include osteocalcin (OC), matrix Gla protein (MGP), Gla-rich protein (GRP), proline-rich Gla proteins, periostin, periostinlike factor (PLF), TGFBI, and growth arrest specific 6 (Gas6). Undercarboxylation of these proteins has been linked to a variety of age-associated conditions, including loss of bone mineral density, increase in fracture risk, osteoarthritis, arterial calcification, insulin resistance, and inflammation.

Vitamin K and Coagulation

The physiological function that led to the discovery of vitamin K, and its confirmation as an essential vitamin for higher vertebrates, was its unique role in the blood clotting cascade. This cascade comprises of a complex series of linked pro-enzyme-to-enzyme conversions, which leads eventually to a fibrin clot. Central to this process is the activation of Gla residues by calcium in some of the members of the cascade series: factors VII, IX, and X and factor II (prothrombin). In addition, there is an inhibitory level of control by proteins C, S, and possibly Z. All seven of these Gla proteins have Gla clusters that interact specifically with calcium so as to alter their polypeptide conformations and to permit their interaction with other members of the coagulation cascade (by exposing a phospholipid-binding domain) and hence leading either to activation or to inhibition of individual components.

Vitamin K and Mineralization

Besides these coagulation factors, there are other extrahepatic VKD proteins associated with bone metabolism and soft tissue calcification.

OC is synthesized specifically by osteoblasts and odontoblasts, and it accounts for *ca.* 15–20% of the noncollagen protein of the bone matrix. Approximately 20% is secreted into blood plasma during bone formation. Circulating OC has frequently been measured as an index of bone-forming (osteblastic) activity, and is present in increased amounts during growth and among individuals with certain bone diseases. It is a small protein, MW 5700, with just three Gla residues. Unlike the blood coagulation Gla proteins, which are almost completely carboxylated in people neither severely vitamin K deficient nor treated with vitamin K antagonist, circulating OC is partially undercarboxylated in most humans, as measured by assays that depend on the affinity of the undercarboxylated form for hydroxyapatite or a specific ELISA assay for the undercarboxylated form. Since vitamin K supplements can reduce its degree of undercarboxylation, it has been proposed as a highly sensitive functional test of vitamin K status in man.

Despite the growing level of interest in its practical use as a status index, our understanding of the essential function of OC remains incomplete. Its affinity for calcium is less strong than that of the larger Gla proteins, but it binds avidly to

hydroxyapatite. Transgenic mice that lack the gene for OC have increased bone mass, despite an increased number of osteoclasts. In humans, however, undercarboxylation of OC, especially in postmenopausal women has been linked to low vitamin K intakes, reduced bone mineral density, and increased risk of fracture. Intervention with high dose MK-4, mainly in Japan, has been reported to improve bone mineral density and decrease fracture risk, although more recent data report has no beneficial effect of MK-4 supplementation on fracture reduction above that achieved from calcium supplementation alone. Randomized clinical trials testing the efficacy of phylloquinone in reducing bone loss in otherwise healthy elderly adults have generally not produced measurable beneficial effects. It is plausible that the associations between high vitamin K intakes and low hip fracture risk are reflective of a healthy diet and lifestyle, and not indicative of causality.

More recently, OC has been reported to be involved in glucose metabolism. Primarily based on data from *in vitro* studies, the uncarboxylated form of OC has been reported to influence β-cell function, insulin sensitivity, adiponectin production, energy expenditure, and adiposity, thus assuming the role of a hormone. The human data are generally limited to small observational studies, and to date are too equivocal to draw conclusions on OC's role in regulation of insulin sensitivity.

The second VKD protein, MGP, having five Gla residues conferring high affinity for calcium and phosphate is a strong inhibitor of calcification and of recognized importance for vascular health. Its synthesis is modulated by 1,25-dihydroxy vitamin D and retinoic acid. Mice lacking the gene for MGP quickly developed calcified arteries and died of aortic rupture before 2 months of age. For this reason, MGP is believed to antagonize the pathological calcification of soft tissues, and thus to protect them. The absence of MGP also led to inappropriate calcification of growth plate cartilage, reduced growth, osteopenia, and fracture in the MGP gene knockout mice. In humans, defects in the MGP gene are associated with Keutel's syndrome and chondroplasia punctata, in which cartilage calcification is abnormal. Similar abnormalities have been observed in infants whose mothers were treated with warfarin during the first trimester of pregnancy. Low vitamin K intake was associated with atherosclerotic calcification of the aorta in postmenopausal women. Also, circulating MGP levels were found to be raised in severe atherosclerosis and in type I diabetes in humans. Measurement of total MGP is not a marker specific to vitamin K activity because vitamin K only influences carboxylation of the protein, and not synthesis. Current immunoassays measuring different elements of MGP carboxylation are in the process of being validated in different populations. More recently, minor alleles of the MGP gene have been reported to confer an increased risk for coronary artery calcification and osteoarthritis.

The third bone-associated Gla protein, protein S, is also involved with blood clotting. It is synthesized by osteoblastlike and osteblastoma cells in culture, and it has been detected in bone matrix. It is also synthesized by hepatocytes, megakaryocytes, and endothelial cells. Children with an inborn deficiency of protein S developed osteopenia and bone lesions; however, its precise functional role is unknown.

Gla-rich protein, GRP, is expressed in most tissues of species studied and, in particular, those containing cartilage and bone cells. GRP contains 16 Gla residues, which is the highest number of Gla residues in any known VKD protein. The high number of Gla residues indicates that this protein has high potential for calcium binding, suggesting its role as a physiological calcium modulator in the extracellular domain.

Periostin and PLF are novel γ-carboxylated proteins. Although known for more than a decade, it is only within the last few years that periostin was identified as a VKD protein. Periostin is highly expressed in bone extracellular matrix and is produced by mesenchymal stromal cells. Periostin is a necessary factor for tissue development, maturation, and repair. PLF, one of the naturally occurring splice variants from the periostin locus, is primarily expressed in the periosteum during the early adaptive stage of remodeling.

Gas6 and Other VKD Gla Proteins

Gas6 is associated with the central nervous system. It acts as a ligand for a number of receptor protein kinases; it potentiates the growth of vascular smooth muscle cells, Schwann cells, and the neurons that synthesize gonadotropin-releasing hormones; and it can prevent apoptotic cell death. Knockout mice in which three Gas6 receptors were mutated had major neurological and spermatogenic abnormalities. There is interest in potential roles for Gas6 in Alzheimer's disease and Parkinson's disease. Clearly, these properties and emerging roles have helped to confirm the growing suspicion that VKD proteins possess key functions beyond blood clotting and even bone remodeling.

There are several other Gla proteins from a variety of tissues that are even less well characterized. TGFBI is an extracellular matrix protein only recently recognized to be γ-carboxylated. Knockdown of TGFBI causes mitotic spindle abnormalities and centrosome duplication. Genomic instability is associated with increased cancer risk and also correlates with the risk of metastasis. TGFBI promotes microtubule stability and downregulates genes related with tumor growth.

Proline-rich Gla proteins PRGP-1 and PRGP-2 are found predominantly in the spinal cord and thyroid gland, respectively, but their functions are unknown. Gla proteins occur in most vertebrates and also in molluscs, so their evolutionary appearance in the animal kingdom is probably quite ancient in origin.

Potential Non-Gla Functions of Vitamin K

Vitamin K is thought to be involved in sphingolipid metabolism in certain bacteria by modulating serine palmitoyl transferase, and warfarin treatment decreased brain concentrations of sulfatides and galactocerebroside sulfotransferase activity in animals, which was reversible by vitamin K (either phylloquinone or MK-4). Therefore, it is now thought that vitamin K may be involved in sphingolipid metabolism.

Most recently, vitamin K, in the forms of both phylloquinone and MK-4, has also been reported in both *in vivo* models and in human studies to modulate proinflammatory cytokine production independent of its role as a cofactor. The mechanism underlying the potential influence of vitamin K on

inflammatory cytokine production is unclear, although it may be through the regulation of the transcription factor NF-κB.

There are several functions of MK-4 that are shared by the isolated geranyl–geraniol side chain, which involve the induction of apoptosis of osteoclasts and of certain cancer cells in culture. Depriving certain tumors of vitamin K, both *in vitro* and *in vivo*, seemed to inhibit their growth and metastasis. In contrast, patients at risk of hepatocellular carcinoma had lower incidence of the disease when given high doses of MK-4 compared to those not receiving MK-4. Data from observational studies also suggest that high intakes of long-chain menaquinones may be associated with lower incidence of certain cancers. However, these studies were not designed to test the hypothesis that vitamin K forms reduce cancer incidences, hence should be considered hypothesis-generating at this time. Recent studies have suggested that MK-4, in particular, has a transcriptional regulatory function. MK-4 promotes extracellular matrix formation by activating SXR to upregulate tsukushi (TSK), which plays a role in collagen accumulation. MK-4 and its isolated geranyl–geraniol side chain were also able to suppress the synthesis of prostaglandin E_2, which is a potent bone resorption catalyst. These observations have led to speculations that (i) some of the menaquinones may possess some functions that are not shared by phylloquinone, and (ii) there may be implications for cell proliferation and for cancer risk from variations in the supply of vitamin K. Because phylloquinone is converted to MK-4 in some but not all tissues, it is highly likely that MK-4 has unique roles independent of its function as an enzyme cofactor. However, it is also plausible that phylloquinone is the optimal dietary form because it can be converted to MK-4 in tissues where presumably needed.

Status, Requirements, and Recommended Intakes

A published 'normal' range for plasma phylloquinone, the predominant circulating form of vitamin K among individuals not taking dietary supplements in the US, is 0.25–2.7 nmol l^{-1}, corresponding to approximate average daily intakes of 100 μg per day in men and 80 μg per day in women. As noted earlier, the phylloquinone content of plasma has a short half-life and is strongly correlated with plasma triglycerides. It also has wide intra-individual and inter-individual margins of variation. It is therefore not ideal as a long-term index of status. Alternatives include functional indices such as PIVKA-II (Protein Induced in Vitamin K Antagonism or Absence-Factor II, which is only sensitive to marginal deficiency), and under-carboxylated osteocalcin (ucOC) (which is the most sensitive functional indicator). These functional indices are not totally specific for vitamin K deficiency, although ucOC (for which monoclonal antibodies now exist) does appear to possess reasonably good specificity. Unfortunately, the different commercial kit assays measure different epitopes of OC, which makes harmonization difficult. More recently, use of urinary metabolites has been proposed as a non-invasive, yet sensitive measure of vitamin K status. Unfortunately none of these biomarkers have physiological outcomes on which to base dietary requirements. For example, although one can increase the amount of the OC that is carboxylated through dietary and supplementary vitamin K, there is no consistent concomitant change in bone turnover markers or bone mineral density. PIVKA-II can be indicative of clotting disorders if elevated. However dietary restriction of vitamin K is not known to induce elevated PIVKA-II levels commensurate with abnormal coagulation.

In the US, the Food and Nutrition Board of the National Academy of Sciences has defined an Adequate Intake (AI) of phylloquinone of 90 μg per day for adult women and 120 μg per day for adult men, with proportionately smaller values for children. The guidelines in the UK are 1 μg per kg body weight per day, and the AI in Japan is set at 75 μg per day for adult men, 60 μg per day for women, aged 19–29 years, and 65 μg per day for women 30 years and over. The true requirement based on the role of extrahepatic VKD proteins is still unknown. Since vitamin K is thought to have a wide range of functions in the body in addition to blood clotting, and some of these may have long-term health implications, research on requirements and optimal intakes, with multiple end points, is needed. Metabolic and health-related differences between the menaquinones and phylloquinone also need to be defined.

Population Groups at Risk of Vitamin K Deficiency

Because of the minimal extent of transfer of vitamin K across the placenta, the fetus and newborn infant have much lower circulating vitamin K than adults (typically 30-fold lower). Although low vitamin K levels have not been found to affect the developing fetus in a functionally deleterious way, it is clear that the newborn, and especially the solely breast-fed infant, is at a higher risk of functional deficiency than older infants and adults. In a minority of cases, this can lead to life-threatening or long-term damage associated with intracranial bleeding. Vitamin K deficiency bleeding (VKDB) is divided into three different types depending on their time of presentation. Early VKDB occurs within the first day of life and is generally associated with maternal use of warfarin or anticoagulants that interfere with the vitamin K cycle. Classic VKDB occurs within the first week of life and is usually idiopathic or associated with breastfeeding. Late VKDB occurs after the first week of life and peaks at 3–8 weeks of life. The late form is usually secondary to an underlying disorder such as malabsorption, chronic diarrhea, liver disease, or undiagnosed cholestasis. Breastfeeding is thought to put infants at a higher risk of classic or late VKDB due to low-milk intakes associated with difficulty in establishing adequate lactation coupled with low vitamin K content of breast milk. In Western countries, since the 1950s, it has been routine practice to give prophylactic phylloquinone in a 1 or 2 mg dose at birth, and this has been found to considerably reduce the risk of VKDB. Recent data suggest that lower doses are as effective in reducing PIVKA-II levels associated with vitamin K deficiency as the current doses (0.5–1 mg phylloquinone), but may result in less accumulation of unmetabolized vitamin K. The consequences of unmetabolized vitamin K measured among children receiving the higher therapeutic prophylactic doses are currently unknown. An intramuscular depot dose was found to be highly effective; however, a study in the UK in the 1990s suggested a possible link with childhood cancer.

Despite little subsequent support for this contraindication, the adverse publicity led to a shift in practice toward oral dosing. An oral micellar preparation containing glycholate and lecithin has been developed that has improved absorption characteristics. Another approach toward the prevention of VKDB is through modern commercial formulas, which typically contain 50–125 μg phylloquinone l^{-1} compared to an average intake of 2 μg per day through breast milk.

Antibiotic-treated patients may be at increased risk of developing vitamin K deficiency. Some antibiotics may reduce the production of usable menaquinones by gut bacteria; others, such as cephalosporins, may also exert vitamin K epoxide reductase inhibitory effects. Vitamins A and E in large doses may increase the risk of vitamin K deficiency and its sequelae in susceptible people. Thus, in one study, patients receiving anticoagulant drugs exhibited a further reduction of prothrombin levels if they were given 400 IU α-tocopherol per day for 4 weeks. The microsomal vitamin K-dependent carboxylase enzyme was found to be inhibited by α-tocopheryl quinone and, to a lesser extent, by α-tocopherol. It is also inhibited by other oxygen free radical antagonists. Control of blood clotting with warfarin-type drugs thus requires control of intakes of vitamins A and E as well as vitamin K so as to achieve consistent results.

Currently the elderly are at the greatest risk of very low vitamin K intakes. The health consequences of these low intakes are currently unknown, but are the focus of active research.

Weight loss and weight loss maintenance require a decrease in energy intake (diet), an increase in energy expenditure (exercise and physical activity), or both. Dietary management should encourage healthy eating, that is, an appropriately balanced intake of macro- and micronutrients. For most obese individuals, this will entail not just a decrease in total energy intake, but specifically a decrease in fat intake, together with an increase in complex carbohydrates, fruit, and vegetables. Myriad diets have been popularized as a means of reducing energy intake, but few are recommended as meeting the overall nutritional needs of an obese individual, and many are so restrictive that they clearly could not be followed for more than a few weeks. Increasing exercise and physical activity has benefits beyond those that result from the relatively modest amounts of extra energy expended. These include a beneficial protection from excessive loss of lean body tissue during dieting, improved fitness and psychological health, and a greater likelihood of long-term weight maintenance. Diet and exercise are core components of behavioral treatments; such treatments, based on learning theories, also aim to help individuals become aware of the behaviors that have led to their weight gain, and to develop strategies to alter them. Weight loss can be achieved successfully with all strategies; behavioral therapies that include a strong focus on increasing exercise and activity seem to offer the best chances of long-term success.

The Concept of Desirable Weight

Body weight reflects the additive mass of the various tissues that make up the organism and is a function of energy and nutrient balance over a prolonged period. Positive energy balance will result in weight gain (mainly from deposition of lipid in adipose tissue), whereas prolonged undernutrition will lead to weight loss. For most of human history, the dominant disorder of body weight has been thinness. Thinness, whether from malnutrition or disease, was associated with illness and was often a prelude to death; in societies where food supplies are scarce or seasonal, a high body weight may be seen as a desirable sign of health and probably wealth. In contrast, in developed societies where levels of activity are low and food is plentiful, the growing prevalence of overweight and obesity has been clearly linked to illness and premature mortality. The concept of a desirable weight at which health is optimal and the risk of disease minimal has not been easy to define, largely because of the effects of many other factors such as age, sex, social status, and smoking.

Dietary Management

Dietary management of obesity aims to reduce fat stores by changing eating habits to reduce energy intake below that

 http://dx.doi.org/10.1016/B978-0-12-375083-9.00282-8

required for weight maintenance. The term 'reducing diet' has been coined to describe such diets used to treat the obese. Because many obese individuals may eat a nutritionally inadequate (apart from energy) diet, it is important that advice on energy restriction is accompanied by the prescription of a 'healthy' diet that contains adequate protein, vitamins, calcium, trace elements, and a desirable ratio of complex carbohydrate to fat. Weight loss *per se* is of no medical benefit unless it is maintained, and this will require the obese individual to adhere to a permanent change in eating habits. Many think of a 'diet' as a temporary change in eating habits (often extreme or quirky), a view encouraged by many of the diet books that hold out the promise of easy and instant success. It is essential that the concept of a long-term change in dietary habits be accepted at the start of treatment.

The energy value of weight gained or lost is approximately 31 MJ kg^{-1} (7500 kcal kg^{-1}) because it is composed approximately of three parts fat to one part lean. Thus, a daily energy deficit of 2.1 MJ (500 kcal) will produce a weight loss of approximately 2 kg per month. For the average man or woman, this represents a 20–30% reduction in energy intake, although for the obese the percentage reduction will be smaller. Thus, the severely obese, for example, with a body mass index (BMI) of 35 or more, will need to follow an energy-restricted diet for months rather than weeks to reverse their obesity. As weight is lost, energy requirements fall, in part because of the reduced energetic mass of the person, and also because of adaptive changes in energy expenditure. For this reason, the rate of weight loss will eventually slow and reach a plateau for any fixed level of dietary energy restriction (**Figure 1**).

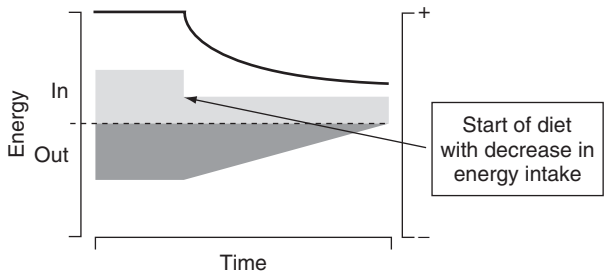

Figure 1 Fall in body weight (solid line) resulting from a fixed decrease in energy intake. Note that the rate of weight loss slows as the gap between energy expenditure (darker shading) and energy intake (lighter shading) narrows.

Myriad diets have been popularized and promoted directly to the public, reflecting every possible permutation of increasing or decreasing the major macronutrients. Fashion and commercialism have dictated many of them. **Table 1** shows the variety of diets that have been suggested, and used, for treating obesity. Many of these diets fail to focus on long-term dietary change, and the quirkiness of many makes it unlikely that they would be followed for long.

Current ideas on a reasonable reducing diet are that it should contain at least 100 g carbohydrate to prevent glycogen depletion and ketosis. High-carbohydrate diets are composed of complex carbohydrates and are thus of low-energy density, which may aid management of hunger. Because high-carbohydrate diets are low in fat, they have the theoretical advantage of directly reducing the risk of cardiovascular disease. The energetic efficiency with which carbohydrate is converted and stored as fat is lower than that of dietary fat, providing a further advantage. Protein intake must be adequate to maintain lean body mass. Although there is an inevitable fall with weight loss, 0.8 g per kg of body weight per day + 1.75 g per 100 cal deficit of protein (approximately 44 g daily for women and 56 g daily for men) should be consumed, and fat restricted to less than 30% of total energy. The diet should contain recommended daily intakes of vitamins, minerals, and electrolytes, if necessary by supplementation; 20–30 g daily of fiber should also be consumed.

Table 1 Types of diet used for treating obesity

Generic name for diet	*Typical dietetic modification*	*Popular example of diet*
Starvation diet	Less than 1.2 MJ (300 kcal) per day	Grapefruit and black coffee
Very low-energy (protein-sparing) diets[a]	Approximately 2 MJ (500 kcal) per day with >50 g high-quality protein; usually liquid	Cambridge diet modifast
Low-energy diet[a]	5–7.5 MJ (1200–1800 kcal) per day often from menus, recipes	Weight watchers TOPS
Fixed-energy deficit diet[a]	Nutritionally balanced, individually tailored to produce fixed-energy deficit (e.g., 2 MJ or 500 kcal day^{-1}) based on measured or predicted energy needs	Prescribed by dietician
High-protein diet	Greater than 40% protein, thus low in carbohydrate and fat	Scarsdale medical diet
Low-protein diet		Beverly hills diet
High-fat diet	Restricted carbohydrate and protein	Drinking man's diet
Low-fat diet[a]	Restrict fat to <20% energy	Prescribed by dietician Pritikin diet
High-carbohydrate diet	Effectively low fat, may be high in fiber	F-plan diet
Low-carbohydrate diet	Limits carbohydrate to maximum <50 g daily	Yudkin diet
Macronutrient choice[a]	Choice from lists of macronutrients to encourage intake of foods high in complex carbohydrates	No counting diet
Meal replacement	Liquid formula meals of approximately 1.7 MJ (400 kcal) to replace 1–2 meals daily	Slim fast
Fad diets	Varied; e.g., food combining diets that require macronutrients to be eaten separately and separated by time	Hay diet

[a]Diets considered medically reasonable under defined circumstances.

Many diets prescribe an energy intake that is based on a generalized rather than an individualized assessment of energy needs. The common prescription of 4.2–5.0 MJ (1000–1200 kcal) daily may be problematic and inappropriate. Weight loss in men will be faster and greater compared with women of equal BMI because of the relatively greater metabolic rate per kilogram of body weight of men. The very obese, whose daily energy requirements can be as high as 12.6 MJ (3000 kcal), may lose weight at an excessive rate and develop symptoms of ketosis, postural hypotension, or excessive hunger. Many obese patients fail to register or admit to the amount of food they consume and claim that such a diet is more than their habitual intake.

One principle of energy prescription that has proved easy to administer and successful in outcome is to calculate energy requirements from standard formulae (**Table 2**) and prescribe a diet that provides a fixed-energy deficit of 2.1 MJ (500 kcal). Compliance and weight loss were better with this approach than with a fixed 5 MJ (1200 kcal) diet.

A diametrically opposite approach is the use of very low-energy liquid diets. These were originally developed in the 1960s to provide a nutritionally complete intake in terms of protein, vitamins, and micronutrients, but provide as little as 1.4 MJ (350 kcal) daily. The inclusion of sufficient high-quality protein was designed to prevent the excessive loss of lean body mass seen with starvation or other ketotic diets, hence the alternative term 'protein-sparing modified fast.' Appropriately selected, well-motivated patients are highly compliant with such diets, and their weight loss can be very rapid. Paradoxically, perhaps, patients seem to find it easier to mount levels of near-total restraint than more moderate restriction. It appears that withdrawing all solid or 'proper' food helps the patient to define himself or herself as 'not eating,' in the same way that some quitting smokers find it easier to abstain completely from cigarettes rather than to cut down.

In the 1970s, a commercial very low-energy diet formulation (the Last Chance Diet) was marketed and was associated with a number of deaths from cardiac arrhythmia. This diet was deficient in essential amino acids and in minerals such as magnesium and potassium. It was withdrawn. In the 1980s newer, better-formulated diets were commercially marketed. Concerns about their inappropriate use by already slim women, often with an eating disorder, forced governmental health agencies to issue guidelines on their use. In the USA, a task force recommended that such diets contain at least 3.3 MJ (800 kcal), be supervised by experienced physicians, and be used only by those with a BMI more than 30, for less than 16 weeks. In the UK, a report from the Committee on Medical Aspects of Food Policy suggested such diets should provide a minimum of 1.7 MJ (400 kcal) and 40 g protein daily for women, and 2.1 MJ (500 kcal) and 50 g protein daily for men and tall women. They were recommended for use only by those with a BMI more than 25 and under medical supervision, for no longer than 4 weeks. The drawback of such diets is that unless they are combined with, or followed by, some other treatment (pharmacological or behavioral), weight regain, often soon and rapid, is almost universal.

More recently, low-energy liquid diets of approximately 3 MJ (750 kcal) daily have been popularized, often as part of an overall behavior modification program (see later), or in the form of sachets intended to be used as meal replacements. Both approaches have been shown to have potential for success in short-term studies lasting up to 1 year.

Exercise and Physical Activity

The term 'physical activity' refers to bodily movement produced by skeletal muscle that results in energy expenditure; it thus includes activities of daily living, as well as leisure activity from sport and exercise. The term 'exercise' refers to planned or structured bodily movements, usually undertaken in leisure time in order to improve fitness (e.g., aerobics), whereas 'sport' is physical activity usually in structured competitive situations (e.g., football). Physical activity at recommended levels (moderate intensity for 30 min for 5 days each week) is associated with many health benefits; these include lower all-cause mortality rates; fewer cardiovascular events, such as myocardial infarction and stroke; and a lower incidence of metabolic disorders, including noninsulin-dependent diabetes mellitus and osteoporosis. Levels of activity have been falling in westernized societies largely because of a decrease in physical activity at work (from increasing mechanization) and increasingly sedentary leisure-time pursuits (such as television viewing). The Allied Dunbar National Fitness Survey of UK showed that 70% of the population are insufficiently active, and a separate UK government survey showed that one in three adults could be classified as sedentary, that is, taking less than half an hour of continuous moderate-intensity physical activity each week (**Figure 2**).

Table 2 Formula for estimating RMR for men and women

Age (years)	*RMR*
Men	
18–30	0.063 × weight in kilogram + 2.896 MJ daily
31–60	0.048 × weight in kilogram + 3.653 MJ daily
>60	0.049 × weight in kilogram + 2.459 MJ daily
Women	
18–30	0.062 × weight in kilogram + 2.036 MJ daily
31–60	0.034 × weight in kilogram + 3.538 MJ daily
>60	0.038 × weight in kilogram + 2.755 MJ daily

The energy expenditure greater than 24 h can be estimated by multiplying by a factor related to activity levels (1.3, sedentary; 1.5, moderate activity; 1.8, physically very active).

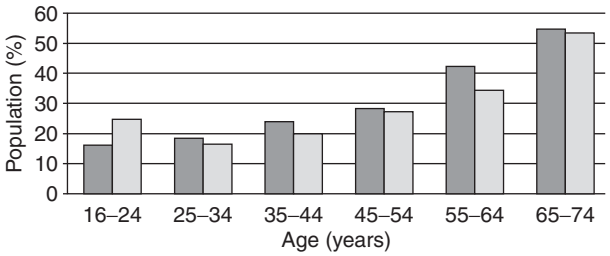

Figure 2 Percentage of adults in England by age and sex (1990–91) with a sedentary lifestyle; dark bars, men; light bars, women. Reproduced from Fentem P and Walker A (1995) Setting targets for England: Challenging, measurable and achievable. In: Killoran A (ed.) *Moving on: International Perspectives on Promoting Physical Activity*. London: Health Education Authority.

Both cross-sectional data and prospective studies confirm an inverse relationship between physical activity and weight gain. The finding that in many countries such as the UK, average-energy intake has fallen over the time that obesity has been increasing, emphasizes the importance of inactivity as a cause of obesity. These secular changes of inactivity are most marked in children who now spend much of their leisure time watching television or in other sedentary pursuits. Health authorities in many countries now advocate an increase in physical activity as a means of preventing obesity and improving health and fitness. Although there is agreement that such measures may be useful in preventing obesity, the role of exercise in treating obesity is less clear. Potential mechanisms linking exercise and activity with weight loss and weight loss maintenance are shown in **Figure 3**. Like dietary change, increasing time spent on exercise and activity can be seen as part of a generalized behavioral change, which can be self-reinforcing.

Exercise and activity raise energy expenditure over and above the resting metabolic rate (RMR). Under some circumstances, such as prolonged vigorous exercise in trained individuals, rates of energy expenditure remain elevated for some time after the cessation of exercise. Logically, therefore, exercise should be a useful way to treat obesity. However, the amounts of exercise-induced energy expenditure are small in comparison with potential changes in energy intake.

The energy cost of activity and exercise can be expressed as a multiple of RMR, termed an MET; the term 'physical activity level' represents the total daily energy expenditure divided by the resting energy expenditure; it typically averages 1.5. The energy costs of walking are approximately 2.0 MET – for a 70-kg individual, this is approximately 0.5 MJ h^{-1} (120 kcal h^{-1}) – whereas gentle running costs are approximately 8 MET or 2 MJ h^{-1} (480 kcal h^{-1}). A moderately fit individual would only be able to maintain a level of exercise of 7 MET for approximately 30 min, representing an additional energy expenditure of approximately 1.5 MJ (360 kcal) resulting, if energy intake were maintained, in a weight loss of approximately 0.3 kg per week.

Energy expenditure remains above baseline for some time after exercise has stopped; this is termed 'postexercise energy expenditure.' The effect is small and only produced by very high levels of activity, capable of achievement only by elite athletes. The mechanism for this effect is unknown. Moderate-intensity exercise programs, of the sort prescribed to the obese, are unlikely to raise energy expenditure by more than approximately 0.2 MJ (50 kcal) per exercise session.

Regular exercise does, however, elevate long-term energy expenditure by its effect on altering body composition. RMR is proportional to the fat-free mass (FFM). Exercise increases muscle development and bone mass, so directly raising metabolic rate. The purpose of weight loss is to reduce fat mass, with as little loss of FFM as possible. The loss of fat to meet the extra-energy requirements of regular exercise will decrease the ratio of fat-to-FFM and thus indirectly favor an increase in RMR for any given body weight. These effects are modest and mainly only seen from the sort of high-intensity exercise achieved by athletes. Even endurance-level training over periods of up to 12 weeks increases nonexercising daily energy expenditure by less than 0.8 MJ (190 kcal).

The effects of exercise are thus quantitatively small. The relatively small potential for exercise to reduce body weight is borne out by the results of trials of exercise in obesity treatment, which suggest that exercise programs achieve weight losses of less than 0.1 kg $week^{-1}$, and that total weight loss averages approximately 3 kg. In one meta-analysis of five controlled trials of exercise without dietary restriction, mean weight loss in 95 men was 2.6 kg over 30 weeks, compared with a gain of 0.4 kg in the control group.

Programs that combine dietary and exercise interventions can be more successful, but it is often difficult to separate the effects of one from the other. To explore the effect of exercise on the composition of weight loss during dieting, Garrow analyzed data from 21 randomized, controlled studies. All trials that

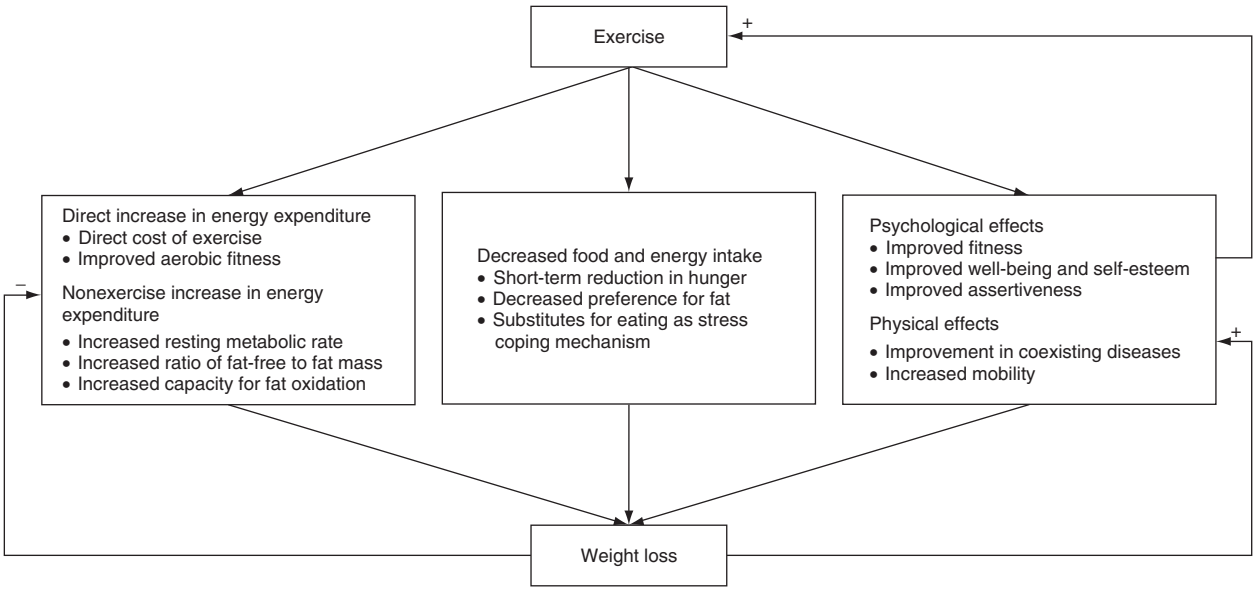

Figure 3 Mechanisms linking exercise with weight loss and weight loss maintenance.

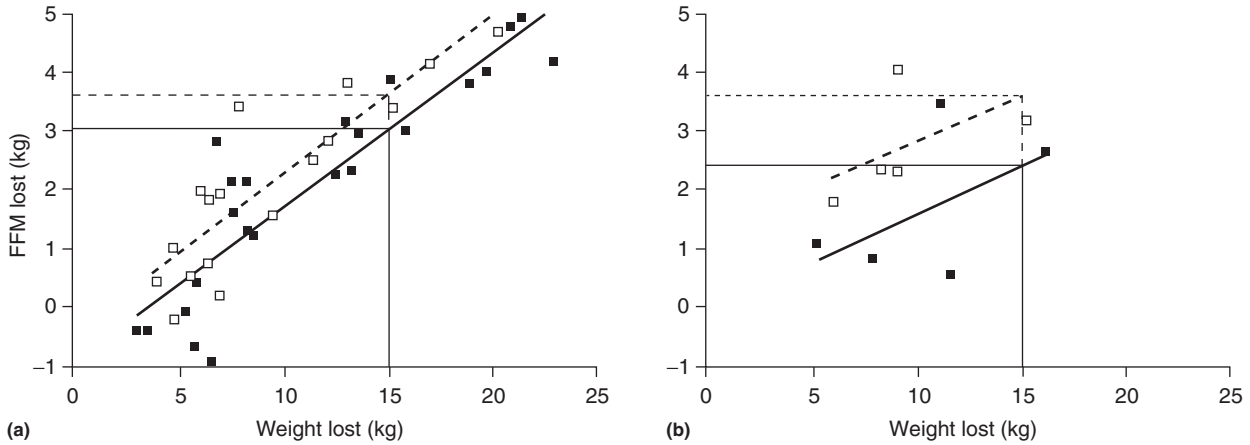

Figure 4 Relationship of total weight loss to FFM loss in (a) women and (b) men undertaking a diet with exercise (solid squares, solid line) or without exercise (open squares, broken line). Reproduced from 21 randomized controlled studies, collated by Garrow JS and Summerbell CD (1995) Meta-analysis: Effect of exercise, with or without dieting, on the body composition of overweight subjects. *European Journal of Clinical Nutrition* 49: 1–10, with permission from Nature.

combined exercise and diet and included information about weight and FFM loss were included (**Figure 4**). A small reduction in the percentage of FFM lost is observed if exercise is included with the dietetic intervention. Thus, for example, in a woman losing 15 kg, exercise would reduce her FFM loss from 3.6 kg (24%) to 3.0 kg (20%). Similar but quantitatively greater benefits are seen in men: For a 15-kg weight loss, exercise reduced FFM loss from 3.6 kg (24%) to 2.5 kg (17%).

Activity and exercise are strong predictors for successful weight loss maintenance. A number of studies have shown that obese women who have lost weight and continue to undertake regular exercise are three to four times more likely to maintain their weight loss over a follow-up period of 2–3 years. The amount of exercise also correlates with the degree of success. In one study of approximately a 100 obese men and women who had lost approximately 27 kg, those with high levels of exercise were maintaining an average of 18 kg loss at 3 years, compared with 9 kg in the moderate exercise group and no weight loss in the nonexercisers. The importance of exercise and weight loss maintenance is demonstrated by a 2-year study of obese subjects treated by either diet, exercise, or a combination of the two. Weight loss in the diet group at 1 year was 6.8 kg, in the exercise group 2.9 kg, and 8.9 kg in the combination treatment group. However, after 2 years, the groups that had included exercise were maintaining losses of 2.2–2.7 kg, whereas those on diet alone had only managed to maintain a 0.9-kg loss. Similar findings have been seen in dieters from commercial slimming groups.

Behavioral Modification

Behavioral modification is seen as the cornerstone of any treatment program that seeks to empower and enable obese individuals to make voluntary changes in lifestyle. Any therapy relies to a greater or lesser extent on such a principle. For example, treating hypertension should be an apparently straightforward clinical management issue, but patient noncompliance with medication is common. The skilled clinician will often include the principles of behavior therapy in consultations to help the patient understand and put into practice the new 'lifestyle' of taking their drugs regularly. The approach in obesity is firmly based on theories of learning and relies on the concept that behaviors associated with weight gain and weight maintenance are to a significant extent learned and subject to modification. Such a behavioral theory is not undermined by the knowledge that genetic and environmental factors are also important in determining the predisposition to obesity. A prerequisite for successful behavior change is that the individual must be 'ready' and motivated to change. It is a common practice to assess this aspect of 'readiness' before enrolling patients in behavioral programs, and a number of standardized and validated questionnaires are available. Because behavioral programs are intensive of therapist time, patients are often treated in groups, often with manuals, which allow for individual study. These groups are usually 'closed,' that is, a small group of patients start the program simultaneously and go through it together. This contrasts with many commercial diet groups, in which patients are free to join or leave at any time. More recently computer-aided interventions have been developed, but as yet results are not promising.

The components of a typical behavior modification program are shown in **Table 3**. For each area, patients need to learn the underlying concepts, recognize the importance to their own situation, and practice strategies to change their behavior. The results of a large number of programs have been published, either as audit outcome or as comparative trials. Programs vary in duration from 12 to 52 weeks (there has been a trend since the 1970s to lengthen treatment time). Dropout rates are clearly biased by selection procedures, but are typically 10–20%. Weight loss during treatment is typically 10–15% of initial weight, at a rate of about 0.5 kg $week^{-1}$. To strengthen the impact of the intervention on weight loss, many programs have included a period of time on very low-energy or liquid-based diets. This approach of a complete withdrawal for a time from established (abnormal) eating habits can be usefully integrated into a model of behavior

Table 3 The components of a typical behavior modification program

Domain	*Intervention strategy*	*Example*
Self-monitoring	Food intake diaries	Food diaries
	Exercise and activity	Activity logs
	Weight change	Regular weighing and recording on weight charts
Nutrition	Nutrition knowledge	Energy, macronutrients, and understanding food labeling
	Healthy eating	Low fat, high complex carbohydrate, and adequate fruit and vegetable intake
Exercise and activity	Increasing daily energy-using activities	Using stairs and not escalators
	Decreasing sedentariness	Decrease television viewing
	Formal exercise	Group workouts at sports centers
Goal setting	Realistic rates of weight loss	Aim for 0.5–1.0 kg weekly
	Realistic target weight	10% weight loss as initial goal
	Weight maintenance	
Problem solving	Identifying conflicts with aims	Holidays, parties, restaurant meals
	Interpersonal conflicts	The unhelpful relative or friend
	Stimulus control and negative feelings	Hunger on returning home from work
Cognitive change	Modifying thoughts about and responses to food cues	Good and bad foods; food as a reward; coping with 'highly desirable' foods
	Self-esteem and assertiveness training	Recognizing and exerting choice
	Preventing relapse	Acceptance of occasional small weight gains

change, and is well and positively tolerated by obese patients. Although data suggest that the greater weight loss induced by very low-energy diets has little effect on the long-term results in terms of weight loss maintenance, these diets do represent a practical and pragmatic initial approach to treating patients in a group, especially when many individuals within such a group may resist the idea that they are able to lose weight on conventional reduced-energy diets.

Research is now directed toward finding ways of improving the results of such programs in terms of long-term weight loss maintenance. An increased focus on weight-maintaining behavior rather than weight loss, a stronger emphasis on increasing activity and exercise, and better relapse strategies are being evaluated. Targeting the needs of specific subgroups, for example, those with binge-eating disorders or dysfunctional family circumstances, is another way in which behavioral therapy may be improved.

Is it better to have lost and re-gained than never to have lost at all? (Weight cycling refrain, loosely adapted from Alfred, Lord Tennyson)

Weight Cycling – A Health Risk?

The term weight cycling is used in the fields of nutrition and obesity research to refer to losses and subsequent regains of body weight typically, but not exclusively, occurring in association with dieting. Interest in this phenomenon was initially based on the observation that conventional weight loss programs are often unsuccessful in the long term. Dieting recidivism thus sets the stage for weight cycling, popularly referred to as yo-yo dieting, whereby dieters undergo multiple cycles of weight loss and regain in pursuit of their ideal body weights.

There seems to be little disagreement that weight cycling is one of the most difficult therapeutic aspects in the management of obesity. Most of the obese subjects seeking treatment have previously experienced cycles of weight loss and regain. Examples of weight cycling in two case studies are shown in Figure 1. These figures illustrate several phenomena that are important when considering weight cycling in humans: Weight losses and subsequent regains occur in conjunction with intentional weight loss dieting; however, weight changes vary in magnitude, and important fluctuations may be missed if weight measurements are taken at infrequent time intervals. Moreover, these two cases illustrate the common observation that intentional weight losses are frequently followed by regains in excess of the original body weight, and that true weight stability may be difficult to achieve.

Dieting to control body weight is not confined to overweight individuals, but has been widely reported even among men and women who have never been overweight. As described by Jeffery in 1984, 72.5% and 43.7% of surveyed women and men, respectively, had dieted to lose weight; even among women who had never been overweight, the majority reported having been on weight-loss diets. Although it is traditionally assumed that adherence to weight-reduction diets is beneficial to health, the high rates of dieting and weight regain, among the nonobese as well as the obese, have naturally created concern regarding potentially negative health consequences. However, weight loss can be intentional or unintentional, and the most recent generation of research on weight cycling has specifically focused on intentional weight loss as the risk factor of relevance to the weight-cycling debate, as reviewed by Simonsen.

In this article, some of the main points of this debate will be highlighted. The first epidemiological studies suggesting health implications of weight cycling were reviewed by Lissner and Brownell, when the majority of available observational evidence indicated adverse consequences. Subsequently, this topic became a source of considerable controversy, and a number of investigators continued to examine this issue, focusing on possible effects of weight cycling on metabolism, chronic disease, and mental health. This article will offer an overview of knowledge in this area, together with some methodological controversies surrounding existing research on weight cycling.

The Metabolic Hypothesis

Given the fact that most people who lose weight are unable to sustain their losses, a 'metabolic' hypothesis was formulated. It was proposed that if weight loss dieting caused permanent decreases in metabolic rate, the weight would be easily regained and every subsequent weight loss attempt would be more difficult. In 1994, the National Task Force on the Prevention and Treatment of Obesity in the US reviewed the evidence and reported an overall lack of support for the hypothesis that weight cycling promoted obesity, increased body fat, or had permanent effects on metabolism. This report also concluded that the majority of available data in animals did not independently link weight cycling to any parameter of energy balance (food intake, body composition, or energy expenditure). This conclusion was supported by studies in humans, using a variety of designs, which failed to document irreversible effects of weight loss on metabolic rate, body composition, or adipose tissue distribution after regain. Also of interest in this context is the observation by Field in 2001 that weight-cycling women, in spite of their regains of lost weight, tended to gain less weight over time than their non-weight-cycling peers. In contrast, Van Wye reported that a history of weight cycling in healthy subjects did not seem to modify the risk of long-term weight gain in men and was associated with marginally more weight gain in women.

Weight Cycling and Mortality

Although most studies did not bear out the original idea that weight cycling alters metabolic rate, the possibility that weight fluctuation predicts chronic disease and death has been more difficult to discount. A number of prospective epidemiological studies have shown that an individual's own variations in body weight over time, a proxy for weight cycling, can statistically predict subsequent risk of mortality and disease. Positive associations have been reported between body weight fluctuation and all-cause mortality in several but not all such studies, as reviewed by the National Task Force on the Prevention and Treatment of Obesity in 1994. These findings are often expressed in terms of relative risk estimates, which represent the mortality rates in a weight-fluctuating group compared with the rates in a weight-stable group. The relative risk estimates for all-cause mortality have been reported to be as high as 2, indicating a double excess mortality risk in the weight-fluctuating

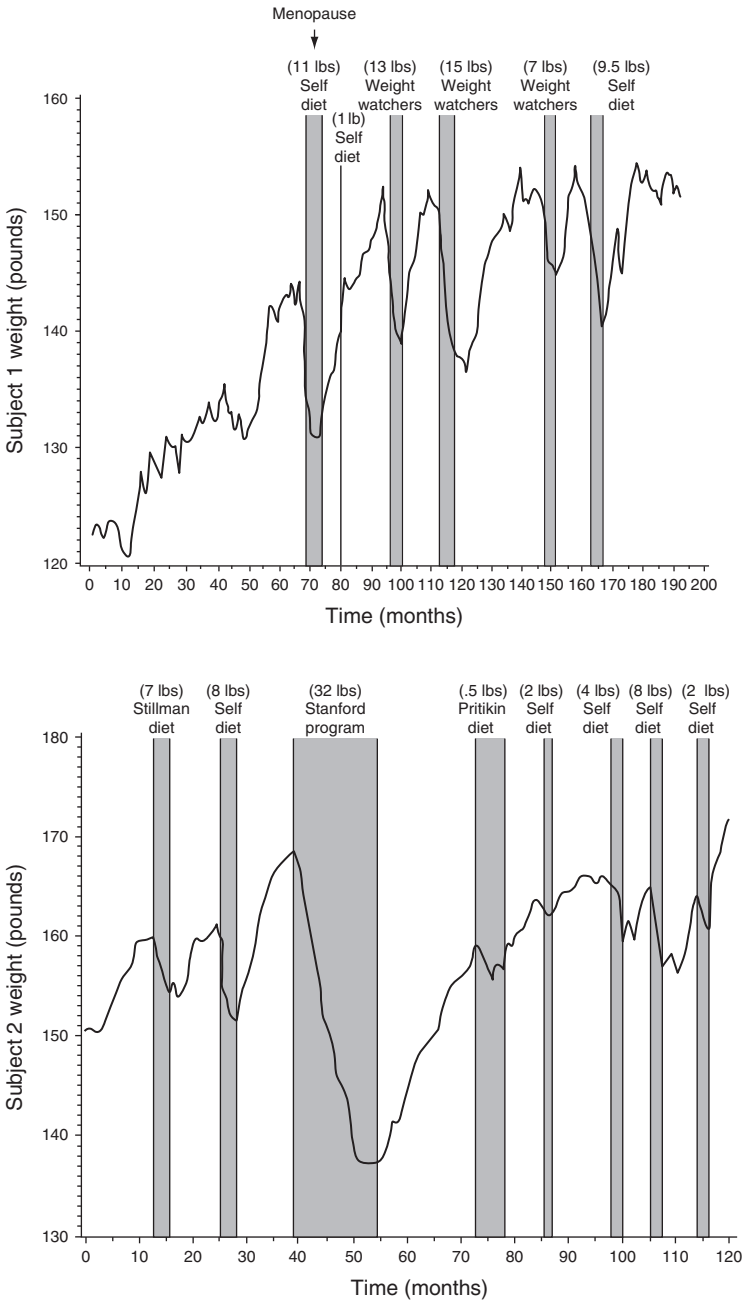

Figure 1 Monthly body weights (average of daily weights) of two female subjects, self-monitored over time. Reproduced from Black DR, Pack DJ, and Hovell MF (1991) A time-series analysis of longitudinal weight changes in two adult women. *International Journal of Obesity* 15: 623–633, with permission from Nature.

individuals. Some investigators have reported that significant associations are restricted to certain types of individual, that is, nonobese or nonsmoking subgroups. For instance, data from the Multiple Risk Factors Intervention Trial (1993) concluded that any adverse effects of weight fluctuation were occurring in relatively normal-weight subjects.

By way of example, results are shown from a reanalysis from a longitudinal population study of Swedish women, started in 1968 when subjects were 38–60 years old. Women were weighed on three occasions over a 12-year observation period, based on which four subcategories of weight change could be created: stable, weight gain, weight loss, and weight cycle. Specifically, these categories were defined as: (1) women whose weights remained stable within plus or minus 3 kg; those who; (2) gained or; (3) lost at least 3 kg between the first and last observation; and (iv) those who had lost and then regained at least 3 kg, or gained then lost 3 kg, without an overall change of more than 3 kg from the first to final observation. When these groups were followed up for an additional 20 years, it was found that the weight-loss group and weight-cycling group both had approximately double risk of mortality, compared with the weight-stable women (**Figure 2**).

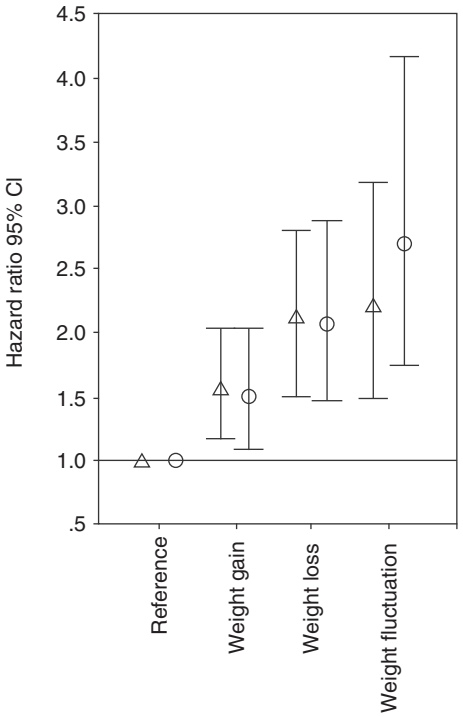

Figure 2 Relative risks of 20-year all-cause mortality, in relation to previous 12-year weight changes in the Prospective Population Study of Women in Göteborg. Triangular symbols refer to risks of total mortality, adjusted for age and final body mass index in 800 women. Circular symbols display results after excluding 99 prevalent cases of coronary heart disease, diabetes, or cancer during 12 years of weight observation.

It may be argued that the weight losses and subsequent gains may not be voluntary but rather reflect preexisting diseases. However, after exclusion of women with prevalent or incident cancer, diabetes, or cardiovascular disease during the entire period of weight observations, the excess mortality in the fluctuating group was not attenuated, suggesting that morbidity from these conditions was not the underlying cause of the fluctuations or reason for the association. These findings and similar observations in a number of other populations have not been adequately explained by biologically plausible mechanisms.

A systematic literature review focusing on intentional weight loss in healthy men and women, rather than weight cycling per se, identified nine studies that could address this issue. The review yielded no consistent evidence that intentional weight loss either increased or decreased mortality. Simonsen concluded that it is still not possible to make secure recommendations that intentional weight loss will increase longevity. This is in contrast to research on severely obese bariatric surgery patients showing improved longevity following elective weight-loss surgery, as reviewed in a recent meta-analysis by Pontiroli. Other factors may influence the associations between intentional weight loss and survival. The age at which weight fluctuations/cycles occurs may be of some relevance as weight loss among the younger adults may be less hazardous than in old age, when even apparently successful weight loss may in fact result from underlying disease. Similarly, weight gain early in adulthood may be more deleterious to overall health and mortality than weight gain later on. However, more research is needed to examine the influence of timing on the relation between weight variations and later disease and death.

Weight Cycling and Cardiovascular Disease

Most investigators have considered it more informative to focus the association between weight fluctuation and specific diseases, and causes of death, and have frequently observed positive associations between weight fluctuation and cardiovascular disease endpoints. However, as reviewed by Lissner and Brownell, the results were not always in agreement; data from the Framingham study showed excess cardiovascular disease among male and female weight-fluctuating individuals, whereas in men from the Baltimore Longitudinal Study on Aging there was no association between weight fluctuation and coronary heart disease. Two additional studies in male populations are illustrated in **Figure 3**. Both show a pattern of elevated risk of mortality from cardiovascular or coronary heart disease among weight-cycling men, and consistently lowest risk associated with stable body weight, based on which Jeffery in 1996 concluded that "stable weight over time is associated with best health. All patterns of weight change other than stable weight – gains, losses, and both combined – appear to be associated with increased mortality risk."

It has been hypothesized that some of the observed associations between weight fluctuation and cardiovascular disease might be explained by changes in cardiovascular risk factors occurring during weight gain that are not fully reversible with weight loss. This possibility has been explored using longitudinal data on body weight and risk factors that are concurrently measured on multiple occasions. A systematic review of these studies by the National Task force on the Prevention and Treatment of Obesity (1994) revealed no consistent associations between weight fluctuation and concomitant increases in traditional cardiovascular disease risk factors such as blood pressure and serum cholesterol.

In particular, hypertension has been examined as an endpoint in a number of studies with somewhat mixed results. Using data from the Nurses' Health Study II, Field and coworkers in 1999 reported that intentional weight cycling was not associated with significant excess risk of development of hypertension. In contrast, a retrospective study by Guagnano indicated that a positive history of weight cycling among obese women as well as the sum of weight regained increased the likelihood of being hypertensive. Interestingly, Stevens reported a possible beneficial effect of one weight cycle: In this blood pressure reduction trial, weight returned to baseline levels after 3 years, although blood pressure remained well below control levels. Control subjects in this study experienced a net weight gain, and one interpretation of this study is that a weight cycle did not predispose further hypertension, but rather, seemed to deter further weight gains at control levels, as also observed in the Nurses' Health Study II (2001). However, intentional weight loss may not have persisting beneficial effects on blood pressure, as shown by the Swedish

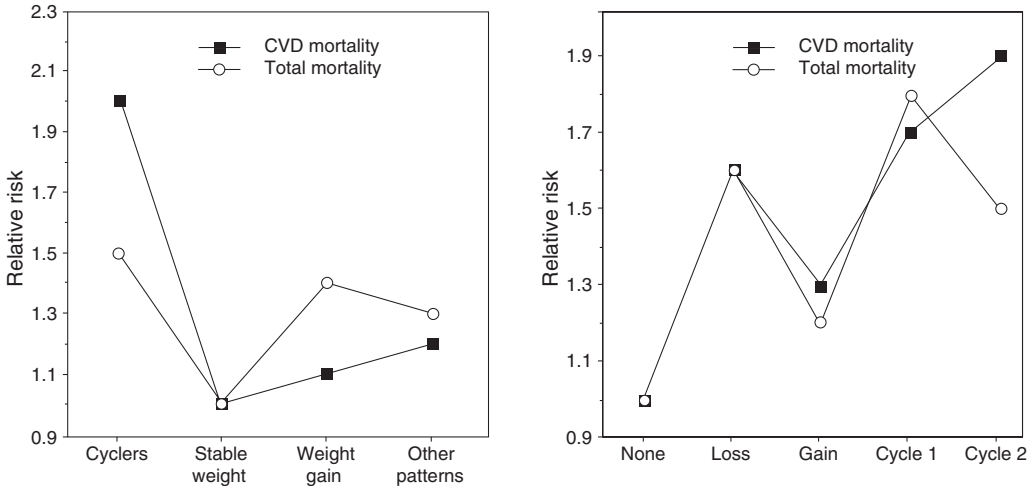

Figure 3 Total and cardiovascular disease mortality in male subjects with different weight change patterns. On the left, data from the Chicago Western Electric Study (Hamm, 1989) and on the right data from MRFIT (Blair, 1991).

Obesity Study (2000) where a large weight loss induced by gastric surgery and maintained over 8 years had no effect on the 8-year incidence of hypertension. In contrast, the beneficial effect on blood pressure was of a transitory nature, with dramatic initial reductions in both systolic and diastolic blood pressure during the initial 12 months of weight loss, and although an 18- to 30-kg weight loss was maintained over the subsequent 7 years, both the systolic and diastolic blood pressure of the surgically treated group increased. After 8 years there was no difference in systolic blood pressure between the surgically treated and the control groups, and diastolic blood pressure ended up higher in the surgical group than in the controls.

Other Health Outcomes: Cancer and Diabetes

Although several of the original weight-cycling studies also tested associations between weight cycling and cancer, cancer endpoints have typically not followed the same patterns as cardiovascular disease. It has been observed by Trentham-Dietz in 2000 that temporary weight cycling (weight loss followed by weight gain) was not associated with increased risk of postmenopausal breast cancer.

A number of studies have examined associations between weight cycling and diabetes, and yielded little evidence of a relation. In 1997, a study by Podar monitored glucose tolerance and weight fluctuations in obese patients, and reported no deterioration directly associated with weight cycling. In the Nurses' Health Study in 2004, no association was found between weight fluctuation and diabetes incidence. Interestingly, the Diabetes Prevention Program Research Group in 2002 found that the diabetes reduction achieved for more than 4 years with a lifestyle intervention was not diminished with the gradual regaining of more than half of the weight lost. This observation is an indication that a period of weight reduction may exert a net benefit for diabetes, even if weight is subsequently regained.

Psychological Consequences

It has often been assumed that the experience of dieting followed by involuntary regain of the lost weight must take a psychological toll, independent of any medical consequences of weight fluctuation. The possible psychological effects of weight cycling among obese persons were the topic of a literature review by Foster, who reported that weight cycling was not associated with depression, other psychopathology, or depressogenic cognitive styles. However, it was observed that weight cycling was associated with decreased perceptions of health and well-being, decreased eating self-efficacy, and weak increases in binge eating severity. Subsequently, Friedman concluded that an individual's perception of being a weight cycler may be more related to psychological problems than the actual number of pounds lost and regained over time. In 2000, the National Task Force on the Prevention and Treatment of Obesity concluded that concerns that dieting induces eating disorders or other psychological dysfunction in overweight and obese adults are generally not supported by empirical studies. A more recent prospective study of weight changes in relation to women's self-rated health found that that weight gain was associated with significant worsening of self-rated health but that weight loss did not result in an improvement in the same index. The observation that initially poor self-rated health actually predicted more weight gain suggests that causality is not simple, but that the association is more likely to be bidirectional.

Methodological Issues

Although a number of studies have shown that increased weight fluctuations are associated with subsequent occurrence of adverse health outcomes, a number of methodological problems make interpretation of these findings difficult. For example, weight gain, weight loss, and weight cycling are often considered separately, but it is almost impossible to determine

their degree of overlap in observational studies. An individual who is observed to be systematically gaining weight at two points in time may experience a number of unmeasured fluctuations in the interim. However, as both loss and gain have been shown to increase risk of dying prematurely, it is possible that the increased mortality risk associated with weight cycling depends on the cumulated risk contributions from repeated weight loss and gain. The statistical complexities in defining weight cycling were reviewed in 1994 by the National Task Force on the Prevention and Treatment of Obesity.

A common observation surrounding this type of research is that different studies may be measuring quite different kinds of weight change – voluntary and involuntary. Involuntary changes may reflect serious underlying illness, depression, and other nondieting phenomena. However, intentional dieting may also occur by a variety of dietary methods, some of which are more detrimental to health than others, as discussed by French in 1993. The issue of volition may shed light on the problem, but the specific impact of previous and current illness on epidemiological associations between weight cycling and longevity is still not fully understood. Other covarying factors besides intentionality of weight change and underlying illness may be producing artifactual associations in observational studies. These include aging, smoking and other lifestyle choices, degree and regional pattern of adiposity, and psychological factors. In epidemiological analyses, various types of statistical corrections can be made for potential confounding factors of this type, although adjustment may be incomplete. Finally, biological plausibility is always an issue to consider when reviewing any epidemiological evidence and has been a particular concern when considering the observations of excess risk in association with weight fluctuations.

Conclusions

As summarized in **Table 1**, many – but not all – epidemiological studies indicate that men and women undergoing body weight fluctuations are at higher risk of mortality and/or cardiovascular disease than individuals experiencing less fluctuation, but the lack of biologically plausible mechanisms to explain these associations has limited the conclusions that can be drawn. Moreover, the evidence for effects on psychological and other health endpoints is inconclusive. Uncontrolled confounding from disease states resulting in a loss–gain or gain–loss pattern must be considered a plausible explanation for some of these findings, underscoring the difficulty of using observational data to study weight cycling. Some studies are suggesting that even limited periods of weight reduction may be beneficial in the long run, whereas others are not. Experimental data and intervention studies are required for confirmation of the weight-cycling hypothesis. The published observational studies of subjects whose weight changes are known to be caused by dieting have been important contributions to the critical discussion of the weight-cycling phenomenon, but additional studies are needed in which weight fluctuations are assessed in a more controlled manner.

Regarding the hypothesis that dieting exacerbates the problem of obesity and weight gain, most studies have failed to demonstrate that weight fluctuation per se depresses metabolic rate. Available research on the effects of weight cycling on both metabolism and disease thus provides little basis to discourage overweight patients from losing weight. Nevertheless, one of the conclusions of the 1994 report from the National Task Force on the Prevention and Treatment of Obesity was that individuals who are not obese and who have no risk factors for obesity-related illness should not undertake weight loss efforts. The only uncontroversial message of the weight-cycling research is that overweight individuals need to be counseled in skills to maintain weight loss, and that relapse prevention should be a more central focus of weight loss programs.

In conclusion, although this research has drawn attention to the necessity of developing improved behavioral and nutritional strategies for sustaining weight reductions and thus preventing weight cycling, the evidence relating weight cycling to adverse health outcomes must be considered equivocal. Regarding the hypothesis that weight cycling exacerbates weight problems, a 1995 opinion survey of obesity researchers conducted by Bray concluded that weight cycling was not considered a very important cause of obesity, and little convincing evidence has emerged in subsequent years to change that conclusion. With regard to the question in the 'weight cycling refrain' regarding possible consequences of weight cycling, the current knowledge would suggest that it is probably not worse to have lost and regained than never to have lost at all. However, there remain some curious and persistent

Table 1 Summary of hypothesized weight cycling effects and selected sources of evidence

Hypothesized adverse health consequences of weight cycling	*Comments (with suggested reading)*
Psychological consequences	Not supported by evidence (reviewed by the US National Task Force, 2000)
Metabolic rate and body composition	Not supported by evidence (reviewed by the US National Task Force, 1994)
All-cause mortality	Supported by most prospective studies, for example, Hamm, 1989; Lissner, 1991; Blair, 1993 (reviewed in Obesity 1992, and by the US National Task Force, 1994)
Cardiovascular disease	Supported by most prospective studies, for example, Hamm, 1989; Lissner, 1991; Blair, 1993 (reviewed in Obesity 1992 and the US National Task Force, 1994)
Diabetes	Not supported by epidemiological studies (Field, 2004). Mixed evidence from clinical setting (Guagnano, 2000)
Cancer	Not supported by epidemiological studies (Lissner, 1991; Trentham-Dietz, 2000)

results in the experimental as well as epidemiological literature suggesting that we do not completely understand the phenomenon.

Weight Maintenance

HA Raynor and EA Steeves, University of Tennessee, Knoxville, TN, USA

© 2013 Elsevier Ltd. All rights reserved.

This article is a revision of the previous edition article by H.A. Raynor, R.R. Wing, volume 4, pp. 413–421, © 2005, Elsevier Ltd.

The majority of adults, more than 65%, in the USA are overweight or obese. Obesity negatively impacts on health outcomes and health care costs, and thus there is heightened awareness of the importance of achieving and maintaining a healthy weight. The goal of this article is to review information obtained from observational and experimental studies on successful weight loss maintenance. A definition and the prevalence of successful weight loss maintenance are provided, and then theories regarding why weight loss maintenance may be difficult are discussed. Next, factors important for successful weight loss maintenance, identified in research examining weight loss maintenance, obtained from the National Weight Control Registry (NWCR) and from randomized controlled trials examining long-term weight loss and weight loss maintenance, are described. The article concludes with general recommendations for achieving successful weight loss maintenance.

Definition of Successful Weight Loss Maintenance

There is no universally accepted definition of successful weight loss maintenance. One definition, proposed in the ''Clinical Guidelines on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults,'' developed by an expert panel convened by the National Obesity Education Initiative of the National Heart, Lung, and Blood Institute (NHLBI), in cooperation with the National Institute of Diabetes and Digestive and Kidney Diseases in 1995, is that successful weight loss maintenance is a weight regain of <3 kg (6.6 lb) in 2 years, following a 10% reduction in body weight. The criterion of 10% weight loss is recommended because weight losses of this magnitude have been shown to have positive health consequences. The definition assumes that the weight loss is intentional.

Data on Prevalence of Long-term Maintenance of Weight Loss

Most information about long-term maintenance of weight loss comes from obesity treatment studies. A review of published lifestyle intervention trials, which are intervention trials that contain a diet and leisure-time activity goal and use behavior modification strategies to help participants meet these goals, resulted in a mean weight loss of -7.9 kg (-8.5% of initial body weight) from baseline to 6 months. At 6 months, weight loss generally plateaued and remained fairly stable from 6 to 12 months. Weight regain started after 12 months, with approximately a -4 kg (-4% of initial body weight) weight loss maintained at 36 and 48 months.

A study using data from the 1999 to 2006 National Health and Nutrition Examination Survey found that among US adults who reported ever being overweight or obese at some point in their life, 36.5% and 17.3% were able to maintain a weight loss of at least 5% and 10%, respectively, for at least 1 year. This study did not differentiate between intentional and unintentional weight losses.

Why is Weight Loss Maintenance Difficult?

Maintenance of long-term weight loss may be difficult due to a combination of physiological, environmental, and psychological factors. Proposed physiological factors contributing to weight regain include reduced resting metabolic rate, and insulin and leptin resistance. Environmental factors may affect energy balance by promoting either increased intake and/or reduced energy expenditure, causing weight regain to occur. The strong impact that environmental cues have on energy intake and expenditure has recently been acknowledged as Americans are now described to be living in an 'obesogenic environment'. The psychological self-control needed to override these environmental cues may be difficult for most people to sustain over long periods. Finally, during obesity treatment, weight loss itself can provide reinforcement for adherence to eating and activity prescriptions that promote weight loss. During weight loss maintenance, weight loss no longer occurs; therefore, there is less reinforcement of healthy eating and activity behaviors, causing motivation for sustaining these behaviors to decrease.

Research Investigating Successful Weight Loss Maintenance

To increase the prevalence of successful weight loss maintenance, two types of research investigating weight loss maintenance have been conducted: observational and experimental. In observational research, successful weight loss maintainers are identified and information about how they maintain their weight loss is collected. With experimental research, variables that are believed to affect weight status are manipulated and weight change over time is measured.

The National Weight Control Registry

The largest observational study of successful weight loss maintainers is The NWCR. The NWCR, which was started in 1993, is a registry of approximately 5000 self-selected individuals at least 18 years of age who have lost at least 30 pounds and kept it off at least 1 year. On average, these

participants have lost more than 60 pounds and kept it off more than 5.5 years. The registry members are primarily female (77%) and Caucasian (95%).

Although there is marked heterogeneity in the approaches used for weight loss, there appear to be some common themes for weight loss maintenance. The first common element is consumption of a low-calorie, low-fat diet. Registry participants are consuming an average of 1381 kcal day^{-1}, with 24% of calories from fat, 19% from protein, and 56% from carbohydrates. Registry members also report having a highly structured diet: they regularly consume breakfast, have a consistent diet across weekdays and weekends, limit the variety of foods consumed, and they report consuming close to five eating occasions, meals and snacks, per day.

These long-term changes in diet in registry members are accompanied by sustained increases in physical activity (PA). Women in the registry report 2532 kcal $week^{-1}$ of PA and men report 2903 kcal $week^{-1}$. This would be equivalent to 1 h day^{-1} of brisk activity. Almost 70% of registry members engage in walking for PA, and 36.3% report walking plus engaging in another form of PA. More than 85% of registry members use PA to help maintain weight loss.

The final characteristic of registry members is that they weigh themselves regularly. More than 35% weigh themselves daily and an additional 40% weigh themselves at least once a week. Registry members who decreased their frequency of self-weighing in their first year in the registry regained significantly more weight than members whose frequency of self-weighing stayed the same or increased in their first year in the registry. Frequent monitoring of weight may allow individuals to quickly catch small weight gains and institute corrective actions in regards to energy balance behaviors. See **Table 1** for a summary of the strategies that registry members have reported as being helpful for successful weight loss maintenance.

Experimental Studies Examining Weight Loss Maintenance

Randomized controlled trials evaluating specific treatment components also assist with understanding factors that are important to weight loss maintenance. These trials are stronger scientifically because participants are randomly assigned to treatment conditions and all aspects of the intervention are kept constant except the factor under investigation, providing greater ability to determine cause and effect relationships. However, these studies are limited by their short duration (typically 1–2 years) and their relatively small sample size (usually 100–200 participants).

Table 1 Strategies used by successful weight loss maintainers in the NWCR

Area	*Strategy*
Diet	1. Consuming a low-calorie, low-fat diet 2. Having a highly structured diet
Physical activity	1. Engaging in at least 1 h of moderate-intensity physical activity per day
Behavioral tools	1. Self-monitoring of weight

In experimental studies of weight loss maintenance, the primary focus is usually on overall weight loss (from baseline to the end of the study), usually defined as long-term weight loss; rather than on maintenance of weight loss from the end of the initial treatment (typically 6 months) to study end. Overall weight loss is selected as the variable of interest because it is most strongly associated with health impact.

Several strategies have been tested in experimental studies to improve weight loss maintenance. These strategies include focusing on energy balance, in which changes in diet and/or PA are used to create larger energy deficits that produce greater weight loss, or focusing on intensifying behavioral components of interventions so that skills necessary for sustaining weight loss can be maintained over a longer period.

Energy Balance

To produce weight loss, it is necessary to modify energy balance by eating less and/or exercising more. A substantial body of research suggests that the combination of diet plus exercise is most effective for long-term maintenance of weight loss.

Diet

Within the context of diet, weight loss researchers have focused primarily on the level of caloric restriction and the degree of structure in the diet. More recent research has investigated the influence of macronutrient composition of the diet and energy density on weight loss and weight loss maintenance.

The traditional diet associated with lifestyle interventions is a low-calorie, low-fat, balanced diet. Participants are instructed to eat 1000–1500 kcal day^{-1}(low-calorie diet – LCD) depending on their initial body weight and to reduce dietary fat to 20–30% of calories. There are no specific foods that are required or prohibited, but consumption of complex carbohydrates and guidelines based on MyPyramid are stressed. Participants are instructed to self-monitor the calories and fat grams in all foods they consume. Daily self-monitoring of eating is recommended, as adherence to self-monitoring has been shown to be one of the best predictors of maintenance of weight loss.

Very Low-Calorie Diets

Very low-calorie diets (VLCDs) are dietary regimens typically administered in a medically supervised setting, providing less than 800 kcal day^{-1} usually in the form of meal replacements (specially formulated liquid formulas or bars) or lean meats, fish, or poultry. These diets are designed to provide a high percentage of protein to lessen lean muscle mass loses during rapid weight loss. VLCDs have been shown to produce excellent initial weight losses (− 20 kg at 12 weeks); this effect is partly due to the degree of caloric restriction and partly due to decreased dietary variety and the use of portion-controlled foods in these regimens. Given the large initial weight loss produced by VLCDs, it was hoped that combining these diets with behavioral approaches would maximize long-term weight loss. Although VLCDs improve initial weight loss, they do not appear to produce better long-term weight loss than LCDs. Owing to the lack of significant differences in long-term outcomes between VLCDs and LCDs, NHLBI does not support use of VLCDs over LCDs composed of conventional foods.

Structured LCDs

Long-term weight loss maintenance requires continual adherence to reduced energy intake. One approach that has been used to improve long-term adherence to reduced energy intake is to increase the structure of the diet. Several studies have investigated different ways to increase the structure of LCDs, predominantly by limiting food choices and controlling portion sizes consumed.

A study examined whether providing food to participants improved long-term weight loss during a standard behavioral intervention using an LCD. Participants were provided all of the food they should eat for five breakfasts and dinners each week for 18 months. Participants receiving the food provisions had greater weight loss throughout the trial (18 months: -6.4 kg vs. -4.1 kg) than those participants receiving a standard intervention, although both groups had identical calorie goals (1000–1500 kcal day^{-1}). However, even with the greater dietary structure, participants still regained weight during the maintenance phase.

Structure in the diet, by decreasing food choices, can also be increased by providing structured meal plans and detailed grocery lists. One investigation that provided meal plans and grocery lists along with a standard intervention showed greater weight loss than the standard intervention alone. The weight losses achieved with the meal plans were similar to those achieved with food provisions.

Using portion-controlled foods available in the marketplace, such as frozen entrees and meal-replacement products, such as Slim-Fast, also increases dietary structure. When an LCD composed of conventional foods was compared with an LCD using two Slim-Fast meal replacements, two Slim-Fast snack bars, and a healthy dinner, the diet using the Slim-Fast portion-controlled foods produced better weight loss at 3 months (-7.1 kg vs. -1.3 kg). For the next 24 months, both groups were instructed to consume one Slim-Fast meal replacement and snack bar per day. At 27 months, the Slim-Fast group still had better weight loss (-10.4 kg vs. -7.7 kg), and the greater weight loss was maintained at 4 years (-9.5 kg vs. -4.1 kg) in those participants available for the follow-up.

Diet Composition

Although reduced energy intake is necessary for weight loss, the composition of the diet is also believed to impact on weight loss and weight loss maintenance. As the macronutrients have differing satiating qualities, composition of the diet may influence how quickly hunger and fullness develop, which can help with reducing energy intake. However, a lifestyle intervention trial testing the effects of a reduced energy prescription with differing amounts of percent energy from carbohydrate, protein, and fat found that at both 6 and 24 months, all dietary prescriptions produced similar levels of weight loss.

Reducing the energy density (kilocalories/gram weight of food) of the diet may also help individuals maintain long-term decreases in energy intake. Reducing dietary energy density is considered to be a beneficial strategy because it allows for a greater volume of food to be consumed without increases in caloric content, which promotes satiation. A year-long trial was conducted to examine the effects of two strategies to reduce dietary energy density on weight loss in obese women. Over 1 year, the condition that reduced fat and consumed water-rich foods had a lower energy density, reported less hunger, and lost more weight (-7.9 kg vs. -6.4 kg) than the condition that reduced fat only.

Physical Activity

Correlational studies suggest that PA is the single best predictor of long-term weight loss maintenance. Physical activity is important because it increases energy expenditure, but it may also reduce hunger and improve mood. The American College of Sports Medicine emphasizes that there is a dose–response relationship with PA and weight loss, such that with greater amounts of PA, greater weight loss occurs.

In lifestyle intervention trials, PA is usually prescribed at a level of 1000 kcal week^{-1}or 150 min of moderate–intense activity/week; however, the ideal amount of PA for weight loss maintenance is still unknown. Studies have shown that high levels of PA, up to 200–300 min/week^{-1}, may be helpful for long-term weight loss maintenance. A study compared the effect of a standard activity recommendation (1000 kcal week^{-1}) versus a higher PA prescription (2500 kcal week^{-1}, equivalent to walking 75 min for 5 days per week) in a lifestyle intervention. The condition with the higher PA prescription had greater long-term weight loss at 18 months (-6.7 kg vs. -4.1 kg). However, even with the higher exercise prescriptions, participants still regained weight during the maintenance phase.

Strategies for Improving Maintenance of PA

One of the most challenging problems with PA in weight control programs is adherence to activity prescriptions. One way to increase activity adherence is to prescribe activity in short bouts (40 min day^{-1} in four 10-min bouts) rather than in long bouts (40 min day^{-1} in one bout). Although short bouts of exercise improved initial adoption of exercise, short-term bouts did not appear to increase PA adherence or weight loss at 12 and 18 months. Participants have also been provided with personal trainers, supervised walks, home exercise equipment, and financial incentives to improve PA adherence. Although personal trainers and financial incentives did increase attendance at exercise sessions, it neither improved total exercise achieved nor weight loss at 18 months. Providing participants with home exercise equipment has been shown to improve both adherence to PA and weight loss. This suggests that home exercise equipment and other approaches that make exercise more convenient may facilitate long-term adherence, and consequently weight loss maintenance.

Sedentary Activities

In addition to promotion of increased PA, decreasing time spent in sedentary activities is receiving more attention as a potential strategy in promoting weight loss and weight loss maintenance. For the average American adult, time spent in sedentary activities has greatly increased, with the largest contributor being television watching. It is believed that sedentary activities may influence weight in two ways. First, sedentary activities may compete with time for being physically active. Second, television watching often cues eating, and thus may encourage excessive energy intake. Although the research is clear that reducing sedentary activities is an effective weight

control strategy in children, few studies have examined this relationship in adults.

Intensifying the Behavioral Component

Although the research described previously focused on ways to enhance negative energy balance through modifications in diet and PA, other investigations have examined ways to intensify behavioral components in weight loss or weight loss maintenance interventions. These strategies include extending professional contact, use of technology, increasing social support, enhancing motivation using incentives, and use of systems-level interventions.

Extending Professional Contact

The maximum weight loss in a behavioral weight loss intervention is typically attained at 6 months, which also represents the end of the weekly phase of therapy and the start of the less-intense maintenance phase. Weight regain is commonly assumed to be due to a failure to continue practicing effective behavioral techniques when treatment transitions. One way to sustain behavioral strategies is to lengthen treatment or to continue to provide some form of professional contact during the maintenance phase.

Lengthening the initial phase of treatment has been shown to increase initial weight loss. For example, when behavioral treatments of identical content, differing only in length of treatment (20 vs. 40 weeks) are compared, the two programs produce similar weight losses at 20 weeks (− 9.5 kg), but the extended treatment produces greater weight loss at 40 weeks (− 13.6 kg vs. − 6.4 kg). Based on this, several investigators have tried to develop year-long programs, with weekly meetings throughout. Weight losses at the end of the year were 10–14 kg, but attendance became quite poor toward the end of the program and the cost-effectiveness of such long-term weekly programs was questioned. Thus, investigators have considered how best to provide contact after the end of the initial 6 months of weekly contact.

One of the first methods used to extend professional contact during the maintenance phase was using booster sessions. Booster sessions take place on a fairly infrequent basis after treatment, with an increasing interval of time between sessions to fade professional contact (e.g., meeting at months 1, 3, 6, and 12). Booster contacts have yielded inconsistent results. This finding and the fact that better maintenance of weight loss occurs when participants continue to be seen biweekly suggest that patients need a fairly high level of contact during maintenance. Studies using biweekly maintenance programs have found better weight loss maintenance at 18- month (87% vs. 33%) follow-ups, as compared with a control intervention receiving no maintenance component.

Technology

As technology has become more sophisticated, it has been used to help with extending contact, predominantly through the use of the Internet, and to increase ease of self-monitoring weight, dietary intake, and PA. A review of weight loss web-based interventions for adults found that trials examining in-person weight loss interventions followed by an Internet-based maintenance intervention were more successful at producing long-term weight loss than trials that only used Internet-based interventions, with no in-person component. However, as studies to date investigating the use of the Internet in delivering intervention have been highly variable in terms of their methodology, strong conclusions regarding the efficacy of the Internet-based interventions on weight loss and weight loss maintenance are not able to be drawn.

Using devices, such as a personal digital assistant (PDA), are also believed to potentially increase adherence to self-monitoring during a lifestyle intervention. Electronic devices, as compared with written records, may make self-monitoring less tedious and can provide real-time feedback to aid with motivation and support changes in energy balance behaviors. One trial examined the use of a PDA with dietary and exercise software as compared with a paper diary during a lifestyle intervention. At 6 months, the condition that monitored with the PDA and received feedback on goals had a greater proportion of participants reach $>5\%$ weight loss as compared with the paper diary condition (63% vs. 46%). Self-monitoring adherence was also greater with the use of the PDA. As a whole, studies investigating the use of technology suggest that it may be helpful for improving weight loss maintenance, but more research is needed.

Social Support

Another approach for providing long-term support is involving friends and family of participants in the treatment program. Spouses have been included in treatment, but the effects have been mixed. A meta-analysis of the spouse support literature showed a small positive effect through 2–3 months of follow-up. A more recent study examined the effectiveness of natural social support (participants were recruited with three other friends and family members who were all losing weight in the same program) and experimentally created social support (through the use of intragroup activities and intergroup competitions) during a standard behavioral weight loss intervention. Sixty-six percent of participants recruited with a friend and given the social support intervention retained their weight loss in full from month 4 to month 10, compared with 24% of individuals recruited alone and given the standard behavioral intervention, without any social support intervention.

Peer support can also be developed among group members in the same weight loss intervention. Support from other members of the group may explain the finding that group treatment tends to be more successful than individual therapy.

Incentives for Weight Loss and Weight Loss Maintenance

Behavioral interventions used in obesity treatments focus on changing antecedents and consequences of behaviors that influence energy balance. Behaviors that produce negative energy balance, and consequential weight loss, can be reinforced, thereby increasing the likelihood that these behaviors will continue. A systematic review of randomized controlled trials investigating the use of financial incentives in obesity interventions found no significant effect of the use of incentives on weight loss at 12 and 18 months. The review concluded by suggesting future research in this area should target a better understanding of the amount, frequency, and

Table 2 Helpful strategies for successful weight loss maintenance

Area	*Strategy*
Diet	1. Consume an LCD ($\sim$1500 kcal day^{-1}) 2. Consume a low-fat ($<$30% kcal from fat) diet 3. To assist with consuming an LCD, increase structure in the diet using: a. Food provisions b. Meal plans c. Meal replacements 4. Lowering the energy density of the diet may be helpful
Physical activity	1. Be active at a moderate-intensity level for at least 200 min week^{-1} 2. To assist with achieving 200 min week^{-1} a. Have exercise equipment available at home b. Allow activity to accumulate during the day (in at least 10-min bouts)
Self-monitoring	1. Record body weight at least once per week and not more than once per day
Professional contact	1. Extend professional contact beyond initial treatment, occurring at least on a biweekly basis
Technology	1. Technology may be helpful for extending professional contact, as well as increasing the ease of self-monitoring energy balance behaviors
Social support	1. Include support from other individuals also working toward weight loss or weight loss maintenance a. Can be from family, friends, or other members of treatment group

type of incentive that could be motivating to improve long-term weight loss outcomes.

Systems-Level Programs

As little progress has been made in reducing the prevalence of obesity, more emphasis is being placed on developing interventions that can help change energy balance behaviors within the larger context in which people live. Thus, these interventions would help change organizations (i.e., worksites and schools), communities, and policy, such that it makes it easier for individuals to engage in healthy eating and leisure-time activity behaviors. As this is a more recent area of research in weight management, it is not clear yet how best to develop these types of interventions, and how effective they are on long-term weight management.

Conclusion

Successful weight loss maintenance can be challenging. However, information obtained from the NWCR, a registry of long-term successful weight loss maintainers, and from experimental studies, which have examined different approaches to improve weight loss maintenance, indicates that there are several strategies that may assist with long-term weight loss maintenance. These strategies are described in **Table 2**. Most notably, it is vital to recognize that for successful weight loss maintenance, individuals have to continue to consume fewer calories and to engage in a greater level of PA than what they did before weight loss, otherwise they will return to a state of positive energy balance, in which weight (re)gain occurs.

Experimental studies show that at least during the weight loss phase, a structured LCD improves long-term weight loss. Being physically active, for at least 200 min week^{-1}, also seems to aid in successful weight loss maintenance. In formalized behavioral programs, a strategy that improves weight loss maintenance is extending professional contact beyond the initial 6 months of weekly treatments. The use of new technologies, such as the Internet and PDAs, are currently being investigated and show promise for improving weight loss maintenance. Including peer support, during both the weight loss and weight maintenance phases of treatment, can also improve long-term weight loss. Interventions that more broadly influence the overall environment in which people live may help with improving weight management.

To date, studies suggest that effective long-term treatment of obesity may require several different strategies, implemented over an extended period of time. Although these tactics improve long-term weight loss, many patients still regain weight after the initial 6-month treatment. Consequently, further research on improving successful weight loss maintenance is needed.

Glossary

Bran Outer protective coat of a cereal grain which protects the seed from the environment. Rich in dietary fiber, micronutrients, and phytochemicals. 5–15% of grain weight depending on species.

Endosperm Energy source for the growing seed. Contains carbohydrate in the form of starches and other oligosaccharides such as fructans. Protein is found in the extracellular matrix. Source of B-vitamins. 60–85% of grain weight depending on species.

Germ The embryo of the seed, rich in protein, oils, fat soluble vitamins, micronutrients, and phytochemicals. 2–4% of grain weight depending on species.

Phytochemicals Non-nutrient bioactive chemicals naturally found in fruits, vegetables, nuts, legumes, and grains that may have a positive impact on health.

Whole grains Intact, ground. cracked, or flaked kernel after removal of inedible parts such as the hull and the husk. The starchy endosperm, bran, and germ are present in the same relative proportions as they were in the intact kernel.

Introduction

It is universally accepted that eating wholegrains is beneficial to health. Wholegrains are nutrient-dense foods which, in addition to being dominant sources of carbohydrate and protein in the diet, contain a wealth of beneficial nutrients and phytochemicals that can be lost during milling. Consuming wholegrain foods prepared from these flours is, therefore, recommended by government and other health promotion agencies. Evidence for the health benefits of whole grain comes from a range of sources, mostly based on observational or epidemiological studies and a growing number of intervention studies. This evidence will be reviewed in this article, focusing on the relationship between whole grain intake and reduced risk of the common causes of death, cardiovascular disease, type 2 diabetes, and cancer. Possible mechanisms of action including effects on inflammatory status, body weight and body fatness, delivery of antioxidants and phytochemicals in the diet, and delivery of dietary fiber and fermentable carbohydrates to the large intestine will be described.

Definition of Wholegrains

Cereal wholegrains are the seeds of the *Poaceae* (or *Gramineae*) family of grasses which are staple foods in the diets of many. Worldwide, the dominant grains consumed include wheat, rice, maize, barley, rye, and oats. Other minor grains common in some countries include millet, sorghum, teff, triticale, and wild rice (**Table 1**). The 'pseudocereals' amaranth, quinoa, and buckwheat are included in this category because structurally they are very similar to the cereal grasses and are used in similar ways as foods. Various definitions of whole grain have been suggested, largely based on a definition proposed by the AACC International; "whole grains consist of the intact, ground, cracked or flaked caryopsis (kernel) after the removal of inedible parts such as the hull and husk. The principal anatomical components – the starchy endosperm, germ, and bran – are present in the same relative proportions as they exist in the intact kernel." The definitions recognize that in modern milling processes the anatomical components of the grain are fractionated during milling but can be recombined to produce wholemeal flour; there is no evidence that such recombined flours are nutritionally different than traditional stone-ground flours where the grains are crushed without separation of the component fractions.

Structural Components and Composition of Grains

Cereal grains have three principle anatomical components each related to their function within the seed. Within each component there is additional complexity which brings with it unique nutrient profiles (**Figure 1**). The bran is often referred to as a single component of the grain, but as **Figure 1** shows, there are several distinct layers including the pericarp and aleurone layers each further subdivided. Modern milling techniques can be used to sequentially remove these layers each of which provides a range of nutrients to the overall profile, particularly dietary fiber(s), some vitamins and minerals, and phytochemicals.

Bran

The function of the bran is to protect the seed and the tough outer layers provide a physical barrier to the external

 http://dx.doi.org/10.1016/B978-0-12-375083-9.00285-3

environment. Removal of the bran is a vigorous abrasive process known as de-hulling, pearling, or peeling, and millers can adapt the severity of the abrasion to remove more or less of the layers. For some cereal grains, notably barley, the degree of abrasion required to remove the inedible fraction of the grain and the extent of removal is such that the resultant grain can no longer be considered a 'whole grain' using the definition above. Nutritionally, the principle nutrient in bran is dietary fiber and this is predominantly of the insoluble type although there can be significant quantities of soluble fibers such as arabinoxylan found in wheat and rye, and β-glucan which is found in particularly high concentrations in oats and barley. The bran layers are also a principle source of phytochemicals and contribute to the antioxidant potential of grain.

Table 1 Common grains included in the whole grain category

Cereal type	*Scientific name*
Cereal	
Wheat, including spelt, emmer, faro, einkorn, kamut, durums	*Triticum* spp
Rice	*Oryza* spp
Maize (corn)	*Zea mays*
Barley, including hull-less or naked varieties but excluding pearled barley	*Hordeum* spp
Rye, including hull-less or naked varieties	*Secale* spp
Oats	*Avena* spp
Millet	*Brachiaria* spp; *Pennisetum* spp; *Panicum* spp; *Setaria* spp; *Paspalum* spp; *Eleusine* spp; *Echinochloa* spp
Sorghum	*Sorghum* spp
Teff	*Eragrostis* spp
Triticale	*Triticale* spp
Canary seed	*Phalaris arundinacea* and *P. Canariensis*
Job's tears	*Coix lacryma-jobi*
Fonia, Black fonio and Asian Millet	*Digitaria* spp
Wild rice	*Zizania aquatic*
Pseudocereals	
Amaranth	*Amaranthus cordatus*
Quinoa	*Chenopodium quinoa* Willd
Buckwheat	*Faopyrum* spp

Endosperm

Quantitatively, the biggest part of the grain is the endosperm which comprises from approximately 60% up to almost 85% of the cereal grain dry weight, depending on species. The endosperm provides the necessary energy for the growing embryo. Nutritionally, the endosperm is mainly carbohydrate in the form of starches and other oligosaccharides such as fructans. Protein is found in the extracellular matrix, and there are some B vitamins in particular pantothenic acid and riboflavin.

Germ

The germ is the smallest fraction of the grain at approximately 2.5% of the grain weight. The germ is the plant embryo which would form the new plant if germinated and is characterized by a high lipid and protein content. The germ is also a rich source of minerals, particularly potassium, calcium, magnesium, and zinc, and both water- and fat-soluble vitamins including vitamin A, tocopherols, and tocotrienols. The oil content of the germ is prone to oxidation which reduces the storage time for wholegrain flours.

Reproduced with permission from Surget A and Barron C (2005) Histologie du grain de blé. *Industrie des Céréales* 145: 3–7, and Hemery Y, Rouau X, Lullien-Pellerin V, Barron C, and Abecassis J (2007) Dry processes to develop wheat fractions and products with enhanced nutritional quality. *Journal of Cereal Science* 46(3): 327–347.

Wholegrain Foods and Health Claims

Intact wholegrains must be processed before consumption. Mostly this involves milling, but less destructive processes such as rolling, flaking, and cracking are also used. Intact wholegrains are used in small quantities in some mueslis or when added as texture in some breads. Processing of the grains increases digestibility and improves texture, flavor, and cooking characteristics of the products. This, together with the fractionation and reconstitution procedures during milling will, inevitably, result in changes to the gross morphology of the product and most likely the chemical composition. The metabolic consequences of consuming wholegrain foods prepared from crushed and minimally processed flours compared with heavily processed reconstituted flours have not been investigated. One characteristic known to change is the glycemic index (GI) which is higher in foods prepared from finely ground flours.

Currently, there is no universal definition for wholegrain foods although this is important in advising the consumer of the healthfulness of whole grain. The US Food & Drug Administration (FDA) defined a wholegrain food as a product containing >51% whole grain by weight per reference amount customarily consumed (RACC) per day. In Europe, industry has mostly used a similar definition although there is no legislative control. The FDA allowed the first health claim for wholegrain foods which could be used on foods which met this criterion. The 1999 claim was modified in 2003 and is based on the following authoritative statement: "Diets rich in whole grain foods and other plant foods and low in total fat, saturated fat, and cholesterol may reduce the risk of heart disease and some cancers." Similar claims in the UK and Europe followed although the claims in Europe are similarly cumbersome. For example, the Swedish claim certified by the Swedish Nutrition Foundation states: "A healthy lifestyle and a well balanced diet rich in wholegrain products reduces the risk for (coronary) heart disease. The product X is rich in wholegrains (contains Y% of wholegrain)." In 2010, the European Food Safety Authority did not approve a whole grain health claim on the grounds that whole grain was 'insufficiently characterized' meaning that, after a period of grace, health claims on wholegrain foods will no longer be allowed in European-Zone countries.

Recommendations for Whole Grain Consumption and Consumption Patterns

Currently, specific recommendations for whole grain consumption exist only in the USA and Denmark. The US Dietary Guidelines 2010 recommend that at least half of total grain-food intake should be as wholegrains, which for those over 9 years of age is a *minimum* of approximately 3 ounce-equivalents or 48 g per day^{-1}. In Denmark, where there is already a stronger tradition in eating wholegrain foods, the target level for consumption is 75 g per 10 MJ energy consumed. In industrialized countries, average whole grain consumption is much lower than these recommendations. In the USA, for example, Americans eat less than 1 ounce-equivalent of wholegrains per day. For the majority of other countries, with the exception of Scandinavian, Nordic, and some Eastern European Countries, wholegrain consumption is of a similar magnitude. Where specific guidelines on amounts are not specified but food agencies recommend consumers to 'choose wholegrains whenever possible' such as the UK, Switzerland, and Australasia, consumption is also very low. In the UK, for example, data from the National Diet and Nutrition Survey showed that median whole grain intake was less than one serving per day, over 97% of adults did not achieve 48 g day^{-1} and more than 30% of individuals consumed no whole grain at all. Measurement of whole grain intake at the population level is required both for development of public health initiatives and for exploring the consequences of different levels of whole grain intake. However, methods for measuring wholegrain intake are varied and often imprecise. For example, in many earlier studies, dark bread was assumed to be wholegrain bread which may not be the case. The studies which collected data in the early 1990s were not originally designed to investigate wholegrain intake (as the food category was not at that time the focus for research interest), and most relied on the use of food frequency questionnaires to collect data on dietary intake. This makes comparison between the studies difficult although the estimates of intake between the highest and lowest wholegrain consumers are reasonably similar. Some studies have reported intake in grams of wholegrain per day, whereas others have reported intake as servings, requiring additional assumptions on definitions of servings. There are relatively few studies where the whole grain content of foods has been systematically calculated based on recipes and manufacturer information and then applied to population survey data with accurate measures of dietary intake. In many studies, a cut-off of 25% whole grain has been used as an inclusion criterion, compared with the 51% advocated by the FDA. In the UK, data from the National Diet and Nutrition Survey for 2000–2001 using a lower cut-off of 10% whole grain to define wholegrain foods showed that 27% of wholegrain intake was for foods with less than 51% wholegrain.

Wholegrains and Reduction in Disease Risk

Cardiovascular Disease

Deaths from cardiovascular diseases (CVD) account for approximately one-third of deaths globally and morbidities associated with CVD account for significant proportions of health care costs. The inverse relationship between increased wholegrain intake and reduced risk of CVD has been documented in numerous observational studies for all different types of CVD. Many of these data come from very large observational and cohort studies carried out in North America and Europe. When analyzing these data it is important to note that, almost without exception in these studies, higher wholegrain intake is associated with many other indicators of a healthy lifestyle, such as lower smoking status and alcohol intake, higher physical activity, and use of supplements and a generally higher household income. Therefore, there is some suggestion that the relationships observed with whole grain intake are merely indicators of a generally healthier

lifestyle. These confounding factors can be mitigated in multivariate analyses which should be used for data evaluation. Even with these considerations, however, the inverse relationships remain significant and in many cases are paralleled by similar relationships for cereal but not total dietary fiber intake and positive relationships between refined grain intake and increased risk of CVD. Data from observational studies have been subjected to meta-analyses and these show significant and marked reductions in risk of the order of 20–30% reductions in CVD risk between groups with the lowest and highest quintiles of whole grain intake. **Figure 2** summarizes some of these data using the most adjusted models of analysis for some of the large cohort studies investigating CVD incidence as endpoints. The range of reductions in either hazards ratio or relative risk of incident CVD is large at between 18% and 52%. The highest figure is for a study with a smaller number of subjects (535 adult men and women) than the other studies which are based on the largest US cohort studies (Health Professionals Follow-up ($n=42\,850$); Nurses' Health Study (NHS) ($n=75\,521$); Iowa Women's Health Study ($n=34\,491$); and Atherosclerosis Risk in Communities Study ($n=15\,972$)) so should be treated with caution. Functional measures of cardiac health are few, but in one longitudinal study, smaller reductions in minimum coronary artery diameter and a trend for lower progression in mean percent stenosis with higher whole grain intake have been reported.

Type 2 Diabetes

The incidence of type 2 diabetes has increased dramatically in line with the rise in obesity worldwide, and consequences of the epidemic represent a major challenge for health services. The etiology of the disease is complex, including interactions between genes, diet, and lifestyle. The underlying pathology is the development of insulin resistance which has been linked to increased intake of refined carbohydrates along with decreased intake of fiber. Many of the studies to show the relationship between wholegrain intake and CVD risk have been used to explore similar relationships for type 2 diabetes. In these observational studies, whole grain intake is also shown to be inversely related to risk of type 2 diabetes and is also associated with lower concentrations of glucose and insulin where these measures are available. One of the largest combined datasets investigating incidence of type 2 diabetes in relation to whole grain intake is research based on 12–18 years of follow-up of women from NHS I and II. 6486 cases of type 2 diabetes were recorded from 73 327 subjects in NHSI and 88 410 subjects in NHSII. Wholegrain intake in the lowest and highest quintiles of intake was 3.7 and 31.2 g day^{-1} for NHSI and 6.2 and 39.9 g day^{-1} for NHSII, respectively. In a multivariate analysis including BMI, the RR for developing type 2 diabetes for the highest quintile of wholegrain intake compared with the lowest quintile of intake was 0.75 (95% CI 0.68, 0.83) for NHSI and 0.86 (95% CI 0.72, 1.02) for NHSII. Addition of

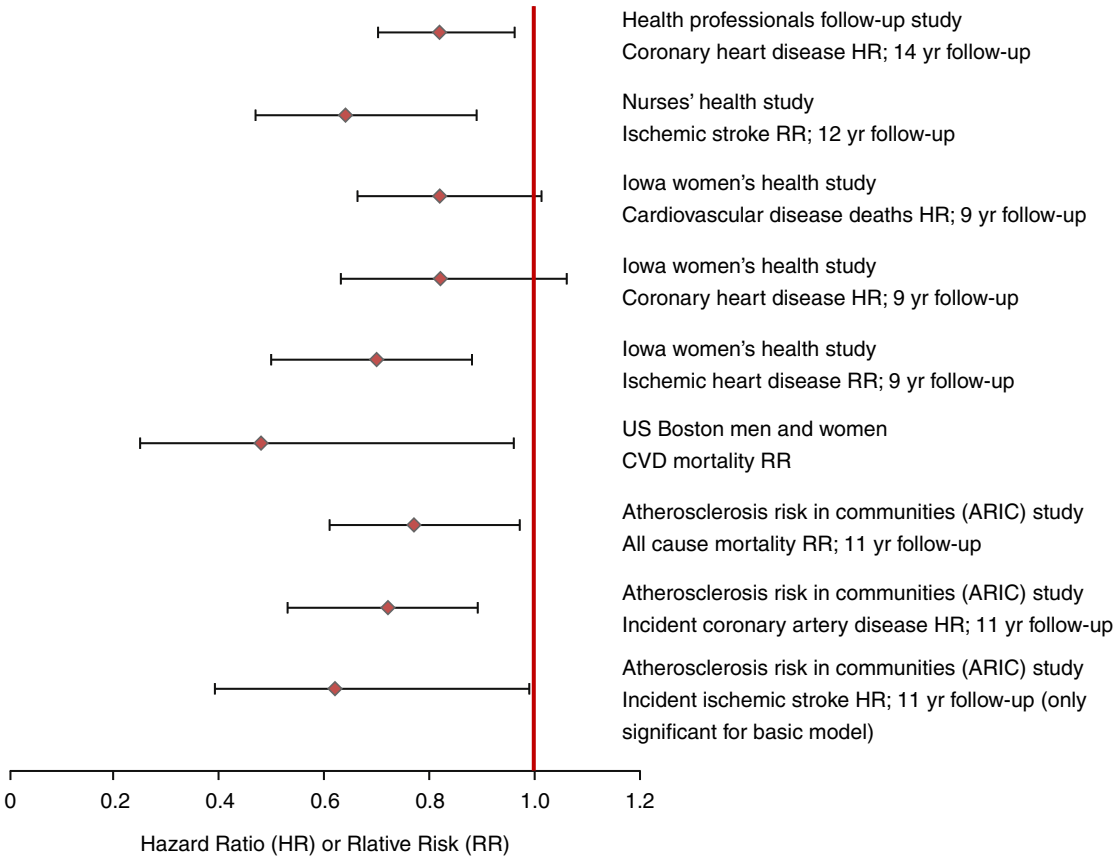

Figure 2 Selection of large-scale observational studies showing a significant ($p<0.05$) benefit of increased whole grain intake on CVD risk. All studies compare the highest versus the lowest whole grain consumers and except where noted are for the most adjusted models.

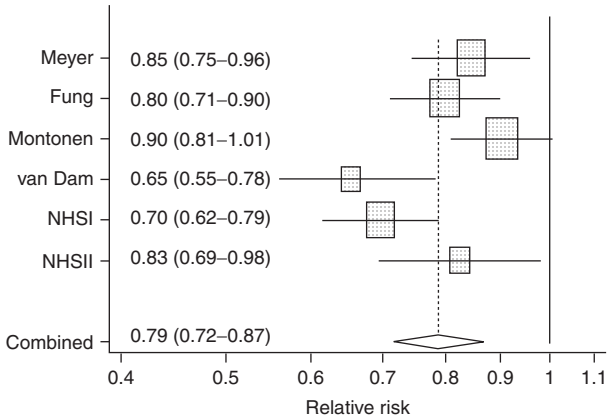

Figure 3 Forest plot showing the multivariate-adjusted RR of type 2 diabetes for a two-servings-per-day increment in whole grain intake for individual cohort studies and all studies combined bars and the diamond indicate 95% CIs. The size of the squares corresponds to the weight of the study in the meta-analysis (De Munter *et al.*, 2007).

data from a further four cohort studies gave a total of 286 125 participants with 10 944 cases of type 2 diabetes; from this full dataset, it was calculated that a two-serving-per-day increment in wholegrain intake was associated with a 21% (95% CI 13, 28) decrease in risk of type 2 diabetes after adjustment for potential confounders and BMI (**Figure 3**).

Intervention studies which have investigated the effect of wholegrain consumption on measures of insulin resistance/sensitivity have given conflicting results. In a very well-designed randomized, nonblinded, 6-week, cross-over dietary intervention with 34 participants, markers of both inflammation and insulin sensitivity were not affected by dietary whole grain compared with the refined grain period. In this study, peripheral insulin sensitivity was determined by the euglycemic hyperinsulinemic glucose clamp method which, although time consuming, is considered the gold standard for this type of measurement. The data showed a 7% reduction in insulin sensitivity in the whole grain group (i.e., insulin resistance increased) although this was not statistically significant. In contrast, in the Multi-Ethnic Study of Atherosclerosis (MESA) study, there was a 9% reduction in insulin resistance with higher whole grain consumption calculated from fasting glucose and insulin concentrations using the homeostatic (HOMA) model of insulin resistance. In another study, employing a tightly controlled dietary regime in a metabolic feeding study with hyperinsulinemic overweight male subjects, insulin sensitivity, again measured by glucose clamp was significantly improved.

Evidence that genetic variability can influence the response to wholegrain consumption is demonstrated in a subset of diabetic subjects compared with control subjects in the European Prospective Investigations into Cancer (EPIC)-Potsdam study. Single-nucleotide polymorphisms in the transcription factor-7-like 2 encoding gene (TCF7L2) were determined for the participants. The TCF7L2 gene is associated with an early insulin secretory defect and has been consistently attributed to the risk of developing type 2 diabetes through the rs7903146 risk-conferring recessive allele (indicated as the T polymorphism compared with the dominant allele C). For the CC genotype, the hazards ratio for 50 g day^{-1} intake of whole grain for development of type 2 diabetes was 0.86 (95% CI 0.75, − 0.99), whereas for the CT and TT genotypes combined the hazards ratio was significantly higher at 1.08 (95% CI 0.96, 1.23). Thus, the beneficial effect of wholegrains in reducing risk of type 2 diabetes was completely attenuated in those carrying the rs7903146 T allele.

Cancer

The protective influence of wholegrains on many cancer sites has been well reported in the literature. Early data were assessed in a meta-analysis and there is a growing body of more recent evidence to support its conclusions. The original meta-analysis collected data from observational studies in the USA (12 studies), Italy (16 studies), and central Europe (12 studies) published between 1984 and 1997. The analysis has some shortcomings, for example whole grain consumption was assessed against mentions of wholegrain foods in broadly descriptive terms. Nevertheless, there were 51 mentions of wholegrains in 40 studies included in the analysis and in 46 of these wholegrains were shown to be protective. When some of the studies were removed from the dataset to remove data with reporting flaws this still left 45 mentions, of which 43 were protective. The associations were strongest for cancers of the gastrointestinal tract as would be expected for these high-fiber foods. For example, for individual cancer types, the odds ratios for disease risk compared between low and high whole grain intake were <1.0 in nine out of 10 studies of colorectal cancers and polyps and all mentions of gastric and other digestive tract cancers. Strong associations were also demonstrated for hormone-related cancers and pancreatic cancer, and a total of eight other cancers. The pooled odds ratio averaged across all studies was 0.66 (95% CI 0.60, 0.72). Data from some of the more recent studies are shown in **Table 2**.

There are considerable data from case-control studies which show a positive association between wholegrain consumption and colorectal cancer risk; however, evidence from prospective studies is limited and contrasting with studies showing both protective and no association between wholegrain intake and risk. Because incidence of colorectal cancer has been shown to be associated with dietary fiber intake, this diversity of results is surprising as wholegrains make a significant contribution to fiber intake. This lack of association may be due to the timescale of some of the studies and the often small number of incident cases identified in the follow-up period. A recent, large, Danish study of men and women from the Diet, Cancer, and Health cohort investigated incident cases of colon cancer and rectal cancer over a median follow-up of 10.6 years. Associations between total and individual whole grain product consumption was examined using data from 461 incident cases of colon cancer and 283 incident cases of rectal cancer among 26 630 men and 29 189 women. Overall, higher total whole grain intake was associated with lower incident relative risk (IRR) of colon cancer and rectal cancer in men. The IRR per 50 g of whole grain intake from the fully adjusted model were 0.85 (95% CI 0.77, 0.94) for colon cancer and 0.90 (95% CI 0.80, 1.01) for rectal cancer. For colon cancer in men, wholegrain wheat bread was the only

Table 2 Observational studies showing a benefit of increased whole grain consumption on cancer risk. All are significant ($p<0.05$) unless stated for fully adjusted model

Study	*Whole grain intake range for comparison*	*Outcome*	*Source*
National Institutes of Health and AARP Diet and Health Study (291 988 men and 197 623 women) 5-year follow-up	0.3 and 1.3 servings per 1000 kcal day^{-1}	Colon cancer: RR 0.86 (95% CI 0.75, 0.99) Distal colon cancer: RR 0.85 (95% CI 0.69, 1.06) Rectal cancer: RR 0.64 (95% CI 0.51, 0.81)	Schatzkin A, Mouw T, Park Y, *et al.* (2007) Dietary fiber and whole-grain consumption in relation to colorectal cancer in the NIH-AARP Diet and Health Study. *American Journal of Clinical Nutrition* 85: 1353–1360.

wholegrain food where the IRR per 25 g of wholegrain wheat bread intake was significantly reduced with higher consumption, IRR 0.89 (95% CI 0.82, 0.97), although there was a trend for rye bread. This response is interesting because the intake of rye bread was approximately twice that of the wheat bread (63 g day^{-1} compared with 31 g day^{-1}) and rye was shown to reduce colon cancer risk in women from the Swedish Mammography Cohort. In the Danish study, there were no consistent associations between total or individual wholegrain food consumption and colon or rectal cancer risk in women which, although this has been seen in some (but not all) studies, was unexpected.

There have been several studies on breast cancer risk and here the data are very variable. Some studies show small,

but modest, benefits of wholegrain consumption, but others show either no benefit or even negative effects of whole grain. Data from the Iowa Women's Health Study suggested that the multivariate-adjusted risk of incident breast cancer was 20% higher for women who had the highest wholegrain intake compared with those with the lowest wholegrain intake. However, when the data were further examined, it appeared that there was no increase in breast cancer incidence in women who had not undergone screening mammography before the follow up suggesting that increasing whole grain intake was associated with more health-conscious behaviors such as attending for cancer screening thus increasing detection rate in whole grain consumers. Recent data from the Danish Diet, Cancer and Health cohort of postmenopausal women also failed to show any association between whole grain intake and breast cancer risk including all estrogen and progesterone receptor disease subtypes. However, in this study whole grain intake was very high; even in the lowest quintile of intake, it was in excess of 70 g of wholegrain food per day which is much higher than intakes reported in other studies. This may suggest a threshold effect for wholegrain benefits which is exceeded in this population.

Wholegrains and Potential Mechanisms of Action

Wholegrains and Inflammatory Status

It is now recognized that chronic subclinical inflammation is central in the progression of many diseases such as CVD and type 2 diabetes. In several cross-sectional studies, the relationship between wholegrain consumption and markers of inflammatory status such as high-sensitivity C-reactive protein (hsCRP), tumor necrosis factor receptor-2 (TNF-R2), fibrinogen, plasminogen activator inhibitor-1 (PAI-1), and interleukin-6 (IL-6) has been investigated. For some of these, inverse relationships have been observed – i.e., increased whole grain consumption is associated with lowered inflammatory marker concentrations. In one weight loss intervention, subjects on a calorie-restricted diet containing wholegrains had lower CRP concentrations than those who only ate refined grain foods. In another study, healthy premenopausal women who ate small amounts of wholegrain (but still less than one serving per day) for 2 years, concentrations of hsCRP were on average 11.5% lower than those who ate no whole grain at all. For women eating one or more servings of wholegrain the reduction in hsCRP concentrations was on average 12.3% lower. These observations, however, have not been found in all intervention studies and the cause and effect relationships are not completely understood although it has been suggested that the responses may be mediated through changes in body weight and adiposity seen in those consuming wholegrains. Improved glucose control has also been suggested as wholegrains may have a slower rate of stomach emptying and decrease carbohydrate digestion. Thus, wholegrain consumption may reduce the time spent in postprandial hyperglycemia reducing the formation of advanced glycation end products which are known to induce oxidative stress and inflammation.

Wholegrains, Body Weight, and Body Fatness

In several, but not all, observational studies, increased wholegrain consumption is associated with lower body mass, BMI, and waist circumference (a measure of abdominal or central obesity). Longitudinal data investigating weight gain over time are available from some of the larger North American cohort studies. For example, women in the NHS were followed from 1984 to 1996 and their habitual diet was assessed every 2 years by a food frequency questionnaire from which the women were divided into quintiles of whole grain intake. Women consuming more wholegrains at baseline weighed less than women consuming fewer wholegrain servings. Women from all quintiles of wholegrain consumption gained weight over the 12 year follow-up period. However, the women who increased their intake of wholegrains during the study gained significantly less weight during the study period. The same trend was found for women who increased their intake of dietary fiber over the follow-up period, suggesting that the fiber content of wholegrain foods may be partly responsible for the protective effect against weight gain. Similar results were found in men in the Health Professionals Follow-up Study. Over an 8-year follow-up period, as with the NHS, all participants tended to gain weight. Wholegrain intake was inversely associated with weight gain, after adjusting for potential confounding variables. Both cereal fiber and fruit fiber (but not vegetable fiber) were also inversely associated with weight gain. Added bran resulted in a dose-dependent reduction in weight gain but added germ did not. Indirect evidence of the benefits of wholegrain foods as part of a healthy food pattern is also seen in the EPIC-Potsdam cohort of German subjects. In this cohort, annual weight gain over a 4-year follow-up was lower with increasing food pattern (more healthy) score; subjects scoring high for the healthy food pattern maintained their weight or gained significantly less weight over time compared with those with a lower (unhealthy) score. Longitudinal changes in overweight and obesity are shown in UK NDNS data. In the 1986/87 survey, whole grain intake was inversely associated with the percentage of men with a BMI $>30\ \mathrm{kg\ m^{-2}}$, independent of other factors. However, intake was not associated with body weight or prevalence of overweight. There were no corresponding associations seen in women. In subjects from the 2000/01 survey, whole grain intake was not associated with body weight, BMI, or waist circumference in men or women. This suggests some dissociation of the relationship between whole grain intake and body weight, but in the 2000/01 survey whole grain intake was significantly lower than in 1986/87 (14 (IQR 0.36) $\mathrm{g\ day^{-1}}$ vs 16 (IQR 0.45) $\mathrm{g\ day^{-1}}$) with significantly more adults consuming no wholegrains in the later survey (29% vs 25%).

Data from the Framingham Heart Study were used to assess the relationship between wholegrain consumption and body fat distribution. The results showed that those from the highest wholegrain consumption group had less subcutaneous abdominal fat (fat under their skin) and less visceral fat (fat around their organs). In contrast, those from the highest refined grain consumption group had more of both types of abdominal fat, especially visceral fat. In a further study involving 434 free-living older adults (60–80 years), percentage

body fat and percentage abdominal fat mass were measured by dual-energy X-ray absorptiometry (DEXA) scanning. After adjustment for covariates, whole grain intake was inversely associated with BMI ($-1\ kg\ m^{-2}$ differences between lowest and highest quartiles of whole grain intake), percentage body fat (-2.4%), and percentage abdominal fat mass (-3.6%). Refined grain intake was not associated with any measure of body fat distribution. There were inverse associations between cereal fiber and BMI ($-1.2\ kg\ m^{-2}$), percentage body fat (-3.2%), and percentage abdominal fat mass (-5%). Thus, cereal fiber, particularly from whole-grain sources, was associated with improved measures of body fatness in these older adults. Body fatness is a risk factor for several chronic diseases. In particular, visceral fat mass is a key indicator of metabolic syndrome, so reduction in visceral fat results in a significant improvement in cardiovascular risk factors. This may be one reason for the health benefits seen for consuming whole grain.

Wholegrains and Blood Pressure

There are a small number of observational studies in which an inverse relationship between hypertension and whole grain intake has been reported. For incident hypertension in men, a relative risk of 0.81 (95% CI: 0.75, 0.87) for those in the highest (median intake 46 g whole grain per day) compared with the lowest (median intake 3 g whole grain per day) quintiles of whole grain intake has been reported. This study, interestingly, was also able to differentiate bran and germ intakes; for the former the relative risk across quintiles of intake was 0.85 (95% CI: 0.78, 0.92) but there was no reduction in risk based on germ intake alone although this may be due to difficulties in quantifying germ intake at the low levels seen for this component of the grain. The effects of whole grain consumption on blood pressure have also been measured in a number of intervention studies with varying results. In two studies from the UK, both randomized control trials with more than 200 healthy volunteers, one showed that 12 weeks consuming three servings per day of wholegrain wheat or a 50:50 mix of whole grain wheat and whole grain oats caused a significant reduction of 6 mmHg in systolic blood pressure and 3 mmHg in pulse pressure. In the second study, however, volunteers consumed either three servings of mixed wholegrains per day for 16 weeks or three servings per day for 8 weeks followed by six servings per day for a further 8 weeks, and blood pressure was not affected in either group. Several studies have used subjects with dyslipidemia, again with varying results. For example, both systolic and diastolic blood pressure were reduced when subjects following a controlled Step I diet for 2 weeks replaced approximately 20% of energy with whole wheat/brown rice, barley, or half wheat-rice/half barley, for 5 weeks compared with a control group consuming no whole grain.

Wholegrains, Antioxidants, and Phytochemicals

Whole grain cereals contain many potentially protective compounds which are lost during the milling process. These include fermentable nonfermentable carbohydrates (dietary fiber), phytochemicals, polyphenolics, and antioxidants. Many of these compounds are found in the bran and germ portions of the grain so are readily lost during even the mildest abrasion. The phytochemicals, polyphenolics, and antioxidants have received particular attention because there are plausible explanations why their consumption may be beneficial for health. For example, antioxidants may have potential to reduce inflammatory responses; phytoestrogens can interact with estrogen receptors and may affect susceptibility to hormone-related cancers.

Phytochemicals are bioactive non-nutrient plant compounds in fruits, vegetables, wholegrains, and other plant foods that have been associated with reduced risk of major chronic diseases and the most studied phytochemicals found in grains are the phenolics. Phenolics are compounds with one or more aromatic rings and one or more hydroxyl groups such as phenolic acids, plant lignans, alkylresorcinols, and flavonoids. Phenolics exist in cereal grains in two forms: soluble free and insoluble bound; the latter include compounds that are esterified to macromolecules and as a result may escape digestion in the upper gastrointestinal tract. It has been suggested that as much as 74% of phenolic compounds in wheat, maize, oats, and barley are found in the insoluble bound fraction. Phenolic compounds mainly exist as glycosides linked to various sugar moieties or as other complexes linked to organic acids, amines, lipids, carbohydrates, and other phenols. There are numerous publications on the phenolics content of cereals and often these may underestimate the true content because they only extract the soluble fraction. These fractions may be released during processing of the grain and be available in the upper part of the intestine or they may be released during bacterial fermentation in the large intestine. Thus, there is potential for local effects in different parts of the gut or systemic effects once the compounds are absorbed. Phenolics and other 'antioxidant' compounds found in cereal grains are able to act as antioxidants because they can donate hydrogen atoms to free radicals. In principle, the higher the amount of phenolics and other antioxidant compounds in cereal grains, the greater their potential antioxidant capacity, and this has been well documented *in vitro* using a variety of assays. However, their potential to affect antioxidant status *in vivo* is rather less certain, and the mechanisms by which antioxidants that cross the intestinal barrier protect the body remain uncertain. Acute feeding studies have shown that ferulic acid, a phenolic found in high concentrations in many cereals, can be absorbed into the blood stream from where it is rapidly excreted. However, in a 2-week randomized cross-over study where men consumed eight servings and women six servings of whole or refined grain foods, antioxidant capacity measured using a range of different methods including markers of oxidative damage did not change.

Lignans are a group of dietary phytoestrogen compounds found in the bran of cereals and some other seeds, legumes, and fruits. The common plant lignans in the human diet include secoisolariciresinol, matairesinol, lariciresinol, pinoresinol, and syringaresinol. Lignans are metabolized by bacteria in the intestine to produce the mammalian lignans, enterodiol, and enterolactone. In several studies, plasma concentrations of enterodiol and enterolactone are positively

correlated with wholegrain intake, and in a Finnish study were inversely correlated with markers of CVD risk and all cause death. These compounds have strong antioxidant activity *in vitro* and weak estrogenic activity that may account for their biological effects on health.

Whole Grain, Dietary Fiber, and Fermentable Carbohydrates

Wholegrains are good sources of dietary fiber, and in observational studies dietary fiber intake is correlated with whole grain intake. The range of complex carbohydrates and nonstarch polysaccharides derived from cereal grains include cellulose, hemicellulose, arabinoxylans, lignin, fructans, such as inulin, and resistant starch. In many of the observational studies described above, health benefits associated with increased wholegrain intake are similarly correlated with cereal fiber intake. The modes of action of wholegrain dietary fiber encompass many physico-chemical and physiological processes all of which can be linked to health benefits ascribed to increased intake of wholegrains. These include direct effects on digesta characteristics such as viscosity, flow rate/transit time, and bulking. These changes then affect digestive processes such as reducing stomach emptying, reducing rates of carbohydrate and lipid digestion, blunting the postprandial glucose and insulin response, lowering glycemic index/glycemic load, binding of bile acids and interrupting the enterohepatic circulation of cholesterol, and delivering fermentable carbohydrate to the large intestine. The potential prebiotic effects of nondigestible oligosaccharides, such as fructans and arabinoxylan fractions, have also been suggested.

Glossary

Bioavailability The proportion of the nutrient content of a food or meal that is absorbed and retained.
Phytate : zinc molar ratio The molar ratio between phytate (molecular weight 660 g mol^{-1}) and zinc (molecular weight 65.4 g mol^{-1}) and is used to estimate the bioavailability of zinc in food and mixed diets.
Phytic acid Myo-inositol hexaphosphate, the principal storage form of phosphorus in many plants and the major inhibitor of zinc absorption (also described as phytate).
Zinc A trace element essential for the human body as it required for the activity of >100 enzymes involved in most major metabolic pathways.
Zinc deficiency Lack of sufficient zinc to meet the physiological requirement.

Causes of Zinc Deficiency

As with other micronutrient deficiencies, four main factors are responsible for the development of zinc deficiency in lower-income countries: inadequate dietary zinc intake; poor zinc absorption from high-phytate, plant-based diets; disease states that either induce excessive losses or impair utilization of zinc; and physiological states that increase zinc requirements, such as the periods of rapid growth during childhood and pregnancy.

Adequate zinc nutrition is essential for human health because of zinc's critical structural and functional roles in multiple enzyme systems that are involved in gene expression, cell division and growth, and immunologic and reproductive functions.

Inadequate Dietary Zinc Intake

Inadequate dietary intake of absorbable zinc is one of the major causes of zinc deficiency. Animal-source foods, in particular shellfish, small whole fish, beef, and organ meats such as liver and kidney, are rich sources of zinc. Plant-source foods, such as most fruits and vegetables including green leaves, and starchy roots and tubers, have relatively low zinc content. Although whole grains, nuts, and legumes have moderate to high zinc content, these foods also contain large quantities of phytate (phytic acid or myo-inositol hexaphosphate), the most potent identified dietary inhibitor of zinc absorption.

Plants synthesize phytate, which occurs in highest concentrations in seeds and to a lesser extent in vegetative plant

parts. Phytate forms chelates with zinc and other minerals, making these minerals less available for absorption. The inhibitory effect of phytate on zinc absorption appears to follow a dose-dependent response, and the phytate : zinc molar ratio can be used to estimate the proportion of absorbable zinc. The phytate : zinc molar ratio of foods or diets is calculated as follows, where 660 equals the molecular weight of phytate and 65.4 the molecular weight of zinc:

$$\frac{\text{mg phytate}/660}{\text{mg zinc}/65.4}$$

The zinc and phytate content, and the phytate : zinc molar ratio in some foods are shown in **Table 1**. If information on the phytate content of the diet cannot be calculated, then diets can be categorized as having low or average zinc bioavailability based on certain dietary characteristics. For example, unrefined cereal and/or legume-based diets generally have phytate : zinc ratios >18, which is associated with relatively low zinc bioavailability. In contrast, mixed diets containing higher amounts of animal-source foods and less plant-source foods, or refined plant-based diets generally have phytate : zinc ratios between 4 and 18, which are associated with higher zinc bioavailability.

Table 1 The average content of zinc and phytate, and the phytate : zinc molar ratio in uncooked foods

Food	*Zinc (mg per 100 g)*	*Phytate (mg per 100 g)*	*Phytate : zinc molar ratio*
Cereals

Other Causes of Zinc Deficiency

Under normal physiological conditions, zinc is secreted into the intestine in large quantities together with digestive juices, but is largely reabsorbed. Diarrhea may not only lead to a reduced absorption of dietary zinc during the episode due to decreased intestinal transit time, but may also cause an increase in the loss of endogenous zinc. Given the important role of the intestine in regulating dietary zinc absorption, and the secretion and reabsorption of endogenous zinc during digestion, conditions that affect the health or integrity of the intestine, such as tropical enteropathy, could interfere with the adequate maintenance of zinc balance. The contribution of these conditions to zinc deficiency in lower-income countries requires investigation.

High Physiological Requirements

In accordance with age and physiological status, some population groups have increased daily physiological requirements for absorbed zinc. During growth and pregnancy, the incorporation of zinc into newly synthesized tissue requires relatively larger amounts of zinc daily. Similarly, the amount of zinc transferred from mother to infant in breastmilk must be added to the lactating women's physiological requirement for absorbed zinc. These increased needs for zinc add to the challenge of acquiring sufficient amounts of absorbable zinc from the food supply. Those groups with higher zinc requirements and who are thus at elevated risk of zinc deficiency include: infants (particularly those born prematurely), young children, children recovering from severe malnutrition or diarrhea, adolescents, and pregnant and lactating women. Some evidence exists for the occurrence of zinc deficiency among each of these groups in lower-income country settings.

The elderly may also be at elevated risk of zinc deficiency, due to a decline in zinc intakes and possibly a reduction in the absorption of dietary zinc. However, evidence for zinc deficiency among the elderly has thus far only been reported from industrialized countries; studies are needed among elderly populations in lower-income countries.

Prevalence of Zinc Deficiency in Developing Countries

Guidelines on the assessment of population zinc status were recently published following a consensus conference convened by the World Health Organization (WHO), the United Nations Children's Fund (UNICEF), the International Atomic Energy Agency (IAEA), and the International Zinc Nutrition

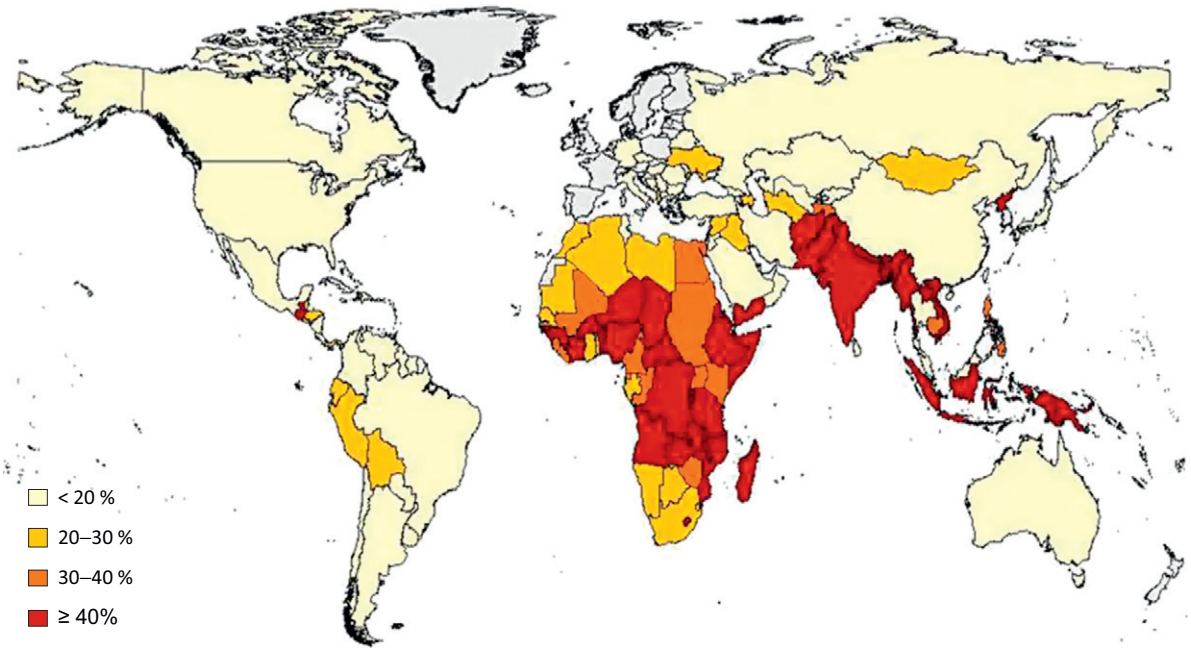

Figure 1 Prevalence of nutritional stunting in children under 5 years of age. Data derived from WHO or most recent Demographic Health Surveys. http://www.izincg.Org/stunning

Consultative Group (IZiNCG). The three main types of zinc status assessment that were considered included biochemical, dietary, and functional methods. Because so little information is available from nationally representative surveys on the prevalence of low serum zinc concentration or inadequate dietary zinc intake, current estimates of the extent of risk of zinc deficiency must rely on the prevalence of stunting among children less than 5 years of age. Approximately 30% of children less than 5 years of age worldwide are stunted (height-for-age Z-score < -2 SD with respect to the distribution of the reference population data). WHO recommends a prevalence of stunting greater than 20% of the population to indicate a public health concern. The highest prevalence rates of stunting ($>30\%$) are observed in countries in sub-Saharan Africa, South Asia, Southeast Asia, and Central America. Intermediate prevalence rates (20–30%) are found in the Andean countries, some Central American countries, Southern Africa, and some countries in North Asia. As zinc deficiency is not the only factor affecting children's growth, assessment of dietary zinc intake and serum zinc levels should be used to confirm the risk of zinc deficiency in these countries. (**Figure 1**)

Consequences of Zinc Deficiency in Developing Countries: Evidence Derived from Zinc Supplementation Trials

In the context of developing country settings, present knowledge on the health consequences of zinc deficiency has been almost entirely derived from community-based trials of zinc supplementation among populations at possible risk of zinc deficiency. In these trials, individuals in the study population are randomly allocated to receive either a zinc supplement, usually in the form of tablets or syrups, or the same supplement format without zinc (i.e., placebo). The condition under study is then monitored for a given period (typically for 2 months to 1 year), and the occurrence of or change in the condition is compared between the zinc-supplemented group and the corresponding control group. Given that several other nutritional and environmental factors can influence the health conditions hypothesized to occur with zinc deficiency, such studies have been essential in demonstrating unequivocally the causal role of zinc deficiency in these conditions among human populations. The following section provides an overview of the population groups at elevated risk of zinc deficiency, and the health consequences associated with zinc deficiency, as concluded from these studies.

Child Growth

Zinc plays an important role in child growth. Several mechanisms may be involved, including the role of zinc in the transcription and translation of genetic material and perhaps more importantly, the regulatory role of zinc in the endocrine system, which controls growth (i.e., the growth hormone–somatomedin axis). Specifically, zinc status is associated with the concentration of circulating insulin-like growth factor-1, the principal growth factor that controls early childhood growth. Among populations where growth restriction occurs, both height and weight gain have improved following supplemental zinc. Stimulation of linear growth appears to be the primary response, while the increase in body weight likely reflects the synthesis of lean tissue, such as bone, cartilage, and muscle, associated with linear growth. This is evident because, in general, weight does not increase independently of improved height in response to zinc supplementation.

According to a recent meta-analysis including 37 studies in infants, preschool, and older prepubertal children, zinc supplementation produces a small, but significant increase in linear growth and weight gain. Zinc deficiency has been demonstrated to be an important limiting factor to the growth of children across a wide range of geographical settings in developing regions. However, it should be noted that not all the studies have demonstrated a significant, positive effect of zinc on growth. Possible explanations for this include: the prevalence or severity of growth stunting in the study communities was low, zinc status was adequate, or deficiencies of other growth-limiting nutrients coexisted thus preventing a positive effect of zinc on growth. The latter situation may also explain the observation in some studies of a transient effect of zinc on growth.

Low-birth-weight infants (<2.5 kg) may have additional needs for zinc, presumably to facilitate their rapid postnatal catch-up growth. Some benefits of supplemental zinc to growth have been observed among low-birth-weight infants in the first 6 months of life.

Severely malnourished infants and children have exhibited improved rates of weight gain, height gain, or synthesis of lean tissue when supplemental zinc has been included in their usual rehabilitation treatment regimen. In these recovering children, zinc has been shown to augment the deposition of lean tissue by increasing protein synthesis. Thus, the inclusion of zinc among other micronutrients is recommended by WHO in the treatment of severely acute malnourished children.

Morbidity and Mortality

Zinc is involved in many aspects of the immune system, contributing both to specific and nonspecific immune functions. Zinc has an important role in both the prevention and treatment of diarrhea, which may be mediated both through functions in immune competence and maintenance of the integrity of the intestine. Preventive zinc supplementation reduces the incidence of diarrhea by approximately 20% among children in lower-income countries, although the current evidence indicates that this beneficial effect of zinc may be limited to children greater than 12 months of age. Zinc also has therapeutic benefits for recovery from diarrheal infections. Overall, supplemental zinc provided to children during either acute or persistent diarrhea leads to a reduction in the duration and possibily the severity of the episode. It has been recommended that zinc should be used in the management of acute diarrhea, in conjunction with oral rehydration salt solution. Zinc deficiency appears to also be associated with an increased incidence of pneumonia. Present evidence from studies that diagnosed acute lower respiratory tract infections (ALRI) based on counting respiratory rate or a physician's examination indicates that preventive zinc supplementation reduces the incidence of pneumonia and ALRI in children by about 21%. Some studies also suggest that zinc supplementation reduces the incidence of malaria, although this remains uncertain because of the limited amount of evidence that is currently available. Based on recent reviews on the impact of zinc on mortality, zinc supplementation reduces the overall mortality rate in children by 6–9%. Similarly to the impact of zinc on diarrhea incidence, the benefits seem to be limited to children above 12 months of age in which the mortality reduction is approximately 18%.

Pregnancy

Zinc requirements during pregnancy have been estimated from the zinc content of accrued tissues during pregnancy. In addition to the zinc transferred to the fetus, zinc is deposited in the placenta, amniotic fluid and uterine, and mammary tissue. The estimated total additional zinc needed for pregnancy is approximately 100 mg. Few firm conclusions can be made as to the consequences of zinc deficiency during pregnancy on maternal, fetal, and infant health. Observational studies in human populations suggest that maternal zinc deficiency during pregnancy may cause adverse pregnancy outcomes for the mother and the fetus. However, results from zinc supplementation trials have been inconsistent and therefore difficult to interpret. This may be partly attributed to an inadequate study design or failure to consider the zinc status of the women studied. Nevertheless, a recent meta-analysis of supplementation trials indicates a 14% reduction in premature delivery among zinc-supplemented women.

Zinc Intervention Strategies

There are numerous zinc intervention strategies available and all have their strengths and weaknesses. While some approaches are considered short-term solutions, others may require a longer period until successful and effective implementation is achieved. In some cases, a combination of these intervention strategies may be needed to ensure the prevention of zinc deficiency in the most vulnerable population groups.

Preventive Zinc Supplementation

As described above, most of the evidences on the beneficial effects of zinc are derived from randomized controlled trials of preventive zinc supplementation and benefits include improved growth, reduced incidence of diarrhea, ALRI, and reduced all-cause mortality. Evidence to date shows no significant adverse effects on indicators of iron and copper status. It has been stated previously that zinc needs to be provided on a daily basis for an extended period of time, although weekly supplementation may also be beneficial. IZiNCG recommends a daily dose of 5 mg zinc for young children. Zinc supplementation is a short-term strategy that relies heavily on the availability of zinc supplements and individual compliance. The challenges for scaling up zinc supplementation programs are similar to those faced by other programs that attempt to procure and distribute nutritional supplements or medicines in lower-income countries. Several existing delivery platforms have been identified, which could be used for delivering preventive zinc supplements with or without other micronutrients. As these programs are being developed, monitoring and evaluation should be included to allow the required assessment of the program's effectiveness.

Therapeutic Zinc Supplementation in the Treatment of Diarrhea

WHO and UNICEF recommend that zinc supplementation should be included as a component in the treatment of all cases of diarrhea. It is recommended to provide children with 20 mg per day of supplemental zinc for 10–14 days (10 mg per day for infants under six months old) along with oral rehydration salt solution and continued feeding. The aim is that the recommendations become routine practice both in the home and health-care facility and that caretakers will act quickly at the first sign of diarrhea. Efforts are underway to reinforce national diarrhea programs and scale up the inclusion of therapeutic zinc supplementation in many countries.

A recent analysis confirmed that there is strong evidence that therapeutic zinc supplementation during diarrhea decreases the duration of diarrheal episodes by ~0.5 day. To what extent the dose of supplemental zinc provided during diarrhea episodes can prevent zinc deficiency is uncertain. Although it is believed that therapeutic zinc supplementation has the potential to prevent future diarrhea episodes following diarrhea treatment, present evidence is weak.

Food Fortification with Zinc

Food fortification is increasingly recognized as an effective approach to improve population's micronutrient status. Available absorption studies clearly show that zinc fortification can increase dietary zinc intake and total daily zinc absorption. Most studies also indicate that adding zinc to food does not adversely affect the sensory properties of the food or the absorption of other micronutrients, such as iron. However, despite the positive effect of zinc fortification on total zinc absorption, the impact as a public health intervention remains unknown.

There are different types of food fortification: foods fortified that are widely consumed by the general population (mass fortification), foods fortified for specific population subgroups, such as complementary foods for young children or rations for displaced populations (targeted fortification), and foods fortified voluntarily by the manufacturers and available in the market place (market-driven fortification).

Mass Fortification of Staple Foods

As described above, mass fortification is the addition of one or more micronutrients to foods commonly consumed by the general public, such as cereals, condiments and milk. Zinc fortification of cereal food staples (wheat flour, maize flour, or rice) is not yet widely practiced, but many new flour fortification programs are beginning to include zinc. Currently, in four countries– Indonesia, Mexico, Jordan, and South Africa–fortification of wheat flour with zinc is mandatory. Thirteen countries include zinc in voluntary wheat flour fortification programs, and five countries have recently proposed new programs that would include zinc. WHO recently adopted guidelines for fortification of wheat flour with zinc. The recommended levels range from 30 to 100 parts per million (ppm) depending on the extraction of the wheat flour and the estimated per capita flour consumption, and the amount of zinc and phytate in the rest of the diet. Although several fortification compounds are generally recognized as safe (GRAS) by the US Food and Drug Administration, zinc oxide is most widely used in food fortification due to its low cost.

Targeted Fortification

Infants from 6 to 24 months of age in lower-income countries are especially vulnerable to deficiencies of zinc and iron because: (1) rapid rate of growth during this period imposes relatively high requirements of these nutrients, (2) breastmilk intakes decrease with age, and the zinc and iron contents of human milk decline to low levels in the second semester postpartum, and (3) most home-available complementary foods are limited in the amounts and bioavailability of these nutrients. Reviews of the theoretical nutrient requirements during the period of complementary feeding indicate that it is very difficult for infants in lower-income countries to meet their requirements for zinc and iron from home-available preparations. One approach is to fortify complementary foods to help meet the physiological needs of young children. However, recent analyses of commercially available fortified complementary foods revealed that the zinc content is in many cases insufficient. Various strategies for 'home' fortification, or point-of-use fortification (POUF), have been developed to ensure adequate micronutrient intakes by infants and young children. These types of products include micronutrient powders, crushable tablets, and lipid-based nutrient supplements, which are added to the complementary food at the time of consumption. To date, there is only inconsistent evidence that zinc fortified complementary foods or POUF can improve zinc status, as measured by biochemical or functional indicators. Whether this is due to the low bioavailability of zinc from cereal-based complementary foods (due to the high phytic acid concentration) or due to other reasons is uncertain.

Dietary Diversification and Modification

The most desirable approach to eliminate zinc deficiency will be to ensure access to diets with adequate zinc content and bioavailability. Dietary diversification and modification have the potential to prevent deficiencies of zinc and other micronutrients. The best strategy for enhancing the zinc content of household diets is to promote the consumption of meat, poultry and fish, all good sources of readily-available zinc. This is because beef, pork, lamb, and liver have a higher content of readily absorbed zinc (3.0 to 6.8 mg of zinc/100 g) than poultry (~1.1 to 2.7 mg of zinc/100 g), eggs (~1.0 to 1.3 mg of zinc/100 g), dairy products (~0.3 to 1.0 mg of zinc/100 g), or finfish (~0.3 to 0.7 mg of zinc/100 g for flesh only; ~3.2 mg of zinc/100 g for whole, soft-boned fish with bones).

Several household food preparation and processing methods can be used to reduce the phytate content of diets based on cereals and legumes. These methods are based on the enzymatic hydrolysis of phytic acid to lower inositol phosphates that occurs during germination and fermentation. A combination of dietary strategies involving increased consumption of animal-source foods and phytate reduction is the preferred method to enhance both the content and bioavailability of zinc in the diets in rural areas of lower-income countries. To be effective, such strategies must be

integrated with ongoing national agriculture, food, nutrition, and health education programs and implemented using a participatory approach to ensure their acceptability, adoption, and sustainability.

Promotion and support of appropriate breastfeeding practices should also be considered among the recommended dietary strategies to enhance the zinc status of infants and young children, for two reasons: breastmilk is an important source of bioavailable zinc, and breastfeeding protects against diarrhea, which causes excessive zinc losses. Public health programs targeting young children should consider the promotion of the three key recommendations: (1) early initiation of breastfeeding, (2) exclusive breastfeeding to 6 months, and (3) continued breastfeeding to 24 months.

Biofortification

Biofortification is an agricultural strategy that aims to increase the content of selected micronutrients, including zinc, in staple foods such as rice, wheat, maize, pearl millet, and others. Biofortification of staple foods can be achieved through the following processes: conventional breeding, by selecting for genotypes with the highest micronutrient content observed for that crop; use of genetic modifications, such as gene insertions or induced mutations; and use of agronomic practices, such as applications of zinc-containing fertilizers. When consumed, biofortified staple foods would lead to improved adequacy of zinc intakes and hence a reduced risk of dietary zinc deficiency, among those who currently have high rates of inadequate intakes. Although the feasibility and efficacy of biofortification to prevent zinc deficiency still needs to be evaluated through efficacy trials, theoretical analyses indicate that it has a potential to improve zinc intakes in adults and children.

Glossary

Acrodermatitis enteropathica A genetic disorder leading to zinc deficiency, associated with mutations in the ZIP4 transporter and impaired zinc absorption.
Metallothionein A small, cysteine-rich zinc binding protein that modulates intracellular zinc homeostasis and acts as an antioxidant.
MTF-1 A zinc-regulated transcription factor.
ZIP transporters A family of zinc transporters responsible for moving zinc into the cytoplasm. Also known as SLC39.
ZnT transporters A family of zinc transporters responsible for moving zinc out of the cytoplasm. Also known as SLC30.

Introduction

Zinc is moderately abundant in nature, ranking 23rd of the elements. Of the trace elements in the body, it is second only to iron, but unlike iron, it has only a single redox state. Together with its size and charge characteristics, this has led to its widespread use within proteins of the body. The number of zinc proteins is unknown but growing, including several hundred enzymes and many more nuclear proteins that regulate gene expression. Additional proteins are responsible for zinc homeostasis. Binding sites and functions of zinc within some of these proteins are well understood, but for others this is less clear. In particular, the links between these biochemical roles of zinc within proteins and its physiological functions are often obscure. The range of physiological functions of zinc is broad and can be observed in all tissues of the body. In general, zinc is required for DNA synthesis, cell division and growth, for protein synthesis and macronutrient metabolism, and for the development and function of most body systems. Lack of an appropriate assessment tool makes it difficult to estimate deficiency prevalence, but undiagnosed marginal zinc deficiency may be a concern.

History of Zinc as a Nutrient

The essentiality of zinc for bacterial growth has been known for almost 150 years. Later, it was shown to be required by plants and then in 1934 for the rat. Because of its broad distribution in the food supply, human zinc deficiency was initially thought to be unlikely. However, in the early 1960s Prasad and others in Iran described a syndrome of dwarfism and lack of sexual development in teenage boys and young adults. The Iranian young men consumed a diet based on unleavened bread with very little animal protein and also ate large amounts of clay (geophagia). They were anemic and responded to treatment with ferrous sulfate, coupled with a more balanced diet including animal protein. The other symptoms also resolved but it seemed unlikely that lack of iron itself was responsible. Prasad then moved to Egypt, where he encountered a similar syndrome. These patients were not geophagic, but ate mostly bread and beans and also were infested with schistomiasis and hookworm. Zinc deficiency was documented in these individuals and treatment with zinc was shown to be more effective at increasing growth rates than either iron or a diet with animal protein. Thus dietary zinc deficiency was demonstrated, presumably due to impaired absorption because of the high fiber and phytate contents of the diet.

Chemistry of Zinc

The conjunction of chemical properties of zinc underlies its biological significance. It is a relatively small ion (atomic number = 30) and carries a positive charge of two. It attracts electrons as a strong Lewis acid and this property can be important in its catalytic functions. It has relatively flexible coordination geometry and while binding its ligands with high affinity, exhibits rapid rates of exchange that can facilitate chemical reactions and biological processes. Its single redox state, in contrast to iron or copper, eliminates danger of oxidative damage. Although other trace elements share some of these properties, none share them all. This is what makes zinc so valuable for protein structure and function.

Zinc in Foods

Zinc is associated with proteins in the body and is found associated with proteins in food. Protein rich foods tend to be good sources (**Table 1**). However, there is great variability, ranging from egg whites, which have almost no zinc, up to oysters at 400 mg kg^{-1}. Legumes and grains have moderate zinc content, though refinement results in large losses, whereas fruits and vegetables are poor sources. Zinc bioavailability is quite variable, due to other food components eaten at the same time. A principal concern is phytate, which renders zinc unavailable. On the other hand, animal proteins appear to enhance zinc absorption, perhaps because amino acids derived from them keep zinc in a soluble form. Enriched breakfast cereals can make significant contributions to zinc intake.

Table 1 Dietary sources of zinc

Food	*Zinc content mg kg^{-1} raw weight*
Oysters	400
Beef, lean	50
Pork	26
Chicken	
Breast	8
Leg	18
Salmon	4
Egg	
Whole	11
White	0.3
Milk	
Whole	4
Cheese	
Cheddar	31
Wheat	
Whole flour	29
White flour	7
Rice	
Brown	20
Polished	12
Breakfast cereals, fortified	100–500
Kidney beans	27
Lentils	36
Potatoes	3
Broccoli	4
Apples	0.4

Control of Zinc Homeostasis

The size and charge characteristics of zinc mandate the use of carriers to traverse biological membranes. Two families of transporters have been described and partially characterized. The ZIP family (also called Solute Carrier 39; SLC39), functions to move zinc into the cytoplasm, either from outside of the cell or from subcellular compartments. The second group of transporters, the ZnT family (SLC30), is responsible for zinc egress from the cytoplasm. Fourteen transporters belonging to the ZIP and 10 belonging to the ZnT family have been identified. Cellular zinc homeostasis is tightly regulated by these transporters in normal and pathological states. For example, the normally zinc-rich prostate exhibits zinc loss with malignancy that is associated with the down regulation of ZIP transporters. ZnT-1 is localized to plasma membranes and functions as a cellular efflux protein. ZnT-2 transports zinc into storage vesicles under conditions of high cellular zinc. Collectively, the ZIP and ZnT proteins are likely to underlie the homeostatic control of zinc distribution around the body.

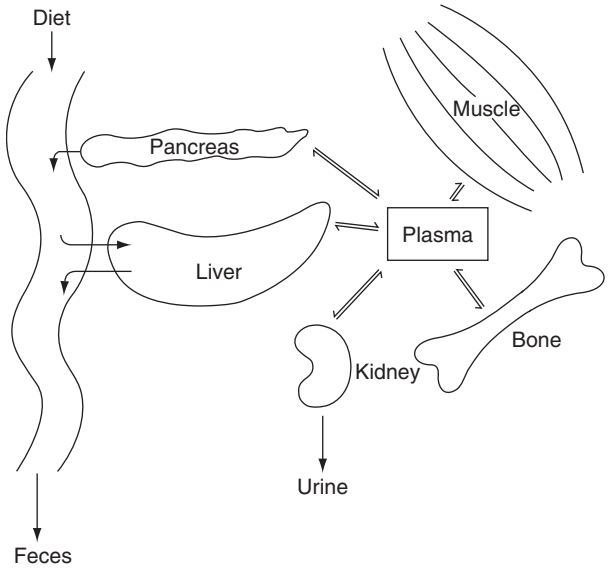

Figure 1 Whole body zinc homeostasis. Zinc in the intestine comes from the diet and endogenous secretions. A portion is absorbed, but much is lost in the feces, which constitute the major site of excretion. Absorbed zinc passes through the liver and then to the general circulation. Zinc is distributed throughout the body with muscle and bone constituting the largest pools. A minor but controlled amount of zinc is lost in the urine.

Zinc Absorption

The absorption, distribution, and excretion of zinc are shown in **Figure 1**. Overall, approximately 20–40% of consumed zinc is absorbed, depending on bioavailability within the particular food source. Zinc is absorbed by both saturable and non-saturable processes, with the greatest rates of absorption occurring in the jejunum. Absorption is adjusted to meet needs, being proportionately increased in deficiency states and reduced when intake is high. Zinc status is reflected by the intestinal concentration of the zinc binding protein, metallothionein (MT). MT may trap zinc within the epithelial cells, causing it to be lost to feces as the cells are sloughed off. This may be part of the explanation of how zinc absorption is adjusted to meet needs. Acrodermatitis enteropathica is an autosomal recessive condition of zinc malabsorption, which can lead to severe deficiency. Gene mutations that lead to this condition have been identified in *ZIP4*, which encodes one of the zinc transporters. This protein has been localized to the apical membrane of intestinal epithelial cells and, given the severity of symptoms associated with its inactivation, appears to be necessary for normal zinc absorption. The zinc efflux protein ZnT-1 is found at the basolateral membrane and so likely promotes passage of zinc out of the intestine. Acrodermatitis enteropathica can be treated with large doses of zinc, supporting the existence of paracellular transport at high intake levels. A large amount of zinc is secreted into the gut from the pancreas and intestine (**Figure 1**). Malabsorption

syndromes can lead to a failure to reabsorb these endogenous secretions and a rapid loss of body zinc.

Transport and Distribution

The zinc plasma pool is relatively small, representing only approximately 0.1% of total body zinc. It circulates bound to albumin and α-2-macroglobulin, with approximately 3% complexed with amino acids. Approximately five-fold greater amounts of zinc are found in whole blood, with erythrocytes accounting for approximately 75% of the total. However, approximately 85% of erythrocyte zinc is complexed within carbonic anhydrase and therefore does not exchange easily. Egress of zinc from the circulation across endothelial cells and into tissues of the body is not well understood. Uptake in association with albumin has been suggested but members of the ZIP family of transporters are likely to play a role here. The tissue distribution of zinc is relatively uniform. All cells require the mineral and no cell stores it. The concentration of zinc in the adult human is approximately 0.5 μmol g^{-1}, giving a total body content of approximately 2 g. More than half is found in skeletal muscle and approximately 30% in bone. The bone pool appears to be more labile than the muscle pool and this has been used as an index of zinc status in experimental animals. Liver represents another labile pool. It receives dietary zinc from the portal circulation and contains approximately 5% of body zinc. At the cellular level, approximately 30–40% zinc is present in the nucleus whereas, 50% of zinc is distributed among the cytoplasm, organelles, and specialized vesicles. The remaining zinc is associated with membranes.

Excretion

Zinc is lost from the body primarily through the feces (**Figure 1**). Feces contain unabsorbed dietary zinc, zinc contained within intestinal epithelial cells, which have been sloughed off, and endogenous secretions into the gut from the pancreas, the gall bladder, and the cells lining the gastro–intestinal tract. The endogenous secretions and the extent to which they are reabsorbed can be controlled and represent an important homeostatic mechanism for regulating zinc status. Zinc losses in urine are relatively minor, but do respond to extremes of intake to help maintain homeostasis. Shed skin cells, sweat, hair, menstrual blood, and semen represent additional routes of loss.

Zinc Biochemistry

Zinc homeostasis and action involves an intimate association of the mineral with proteins. These include membrane transporters responsible for the absorption of zinc in the gut and its passage into and out of cells and subcellular organelles, transport and delivery proteins, both in the circulation and within cells, sensing proteins that adjust homeostasis and function according to zinc availability and then a large range of proteins to which zinc is ultimately delivered. Two major classes of these latter proteins are the enzymes and transcription factors.

Homeostasis

The interaction of zinc with its transporters has not been well characterized, though transmembrane domains have been identified thought to be responsible for the transport function. Free concentrations of zinc within the cell appear to be extremely low and may not constitute a sufficient pool for the supply of zinc to its protein ligands. This implies the existence of delivery proteins, a role suggested for MT, which has been shown to transfer zinc to apoenzymes *in vitro*. MT is a small protein that is unusually cysteine-rich and can bind seven atoms of zinc. It may influence the subcellular distribution and availability of zinc, because its own distribution varies. For example, the nuclear content of MT varies with the cell cycle. MT expression is regulated by zinc and also by a range of other signals including glucocorticoids, interleukins, and cAMP. In addition, its zinc binding activity is influenced by the cellular redox state. For example, an increase in the glutathione disulfide/glutathione ratio results in release of zinc from MT and thus its availability for other proteins.

Investigation of the mechanism whereby zinc regulates the expression of MT led to the discovery of the single protein known to act as a zinc sensor within mammalian cells, MTF-1 (metal response element (MRE)-binding transcription factor-1). MTF-1 binds to MREs in the promoter region of MT and other genes and regulates their expression. The ability of MTF-1 to localize to the nucleus and bind to its target genes is dependent on its zinc content. Thus, an increase in cellular zinc concentrations results in greater MTF-1 activity and elevated expression of its target genes. In addition to MT, which will bind more zinc, these include ZnT-1, which will transport zinc out of the cell. Both actions serve to buffer the increase in cytosolic zinc (**Figure 2**).

Zinc Enzymes

The three-dimensional structures of more than 200 zinc-containing enzymes have now been characterized, and many more have been identified. All six International Union of Biochemistry classes are represented. In some cases (e.g., carbonic anhydrase), zinc is a direct participant in the catalytic function of the enzyme. The zinc atom is coordinated by three amino acids from the enzyme and a molecule of water at the active site. Other enzymes (e.g., protein kinase C) have structural zinc sites, where the metal binds four amino acids within the protein and ensures appropriate folding for bioactivity. For nitric oxide synthase, zinc has been found to serve a bridging function between two separate polypeptides, stabilizing a biologically active larger complex. A selection of zinc enzymes is listed in **Table 2** and help to illustrate the wide variety of metabolic functions requiring zinc.

Zinc Transcription Factors

There are many zinc enzymes but even more transcription factors utilize zinc. Variable numbers of zinc atoms are each coordinated by four cysteine or histidine residues to stabilize a DNA binding structure. A search of the human genome has revealed over 1000 genes (approximately 3% of those identified) containing these characteristic zinc finger domains. An

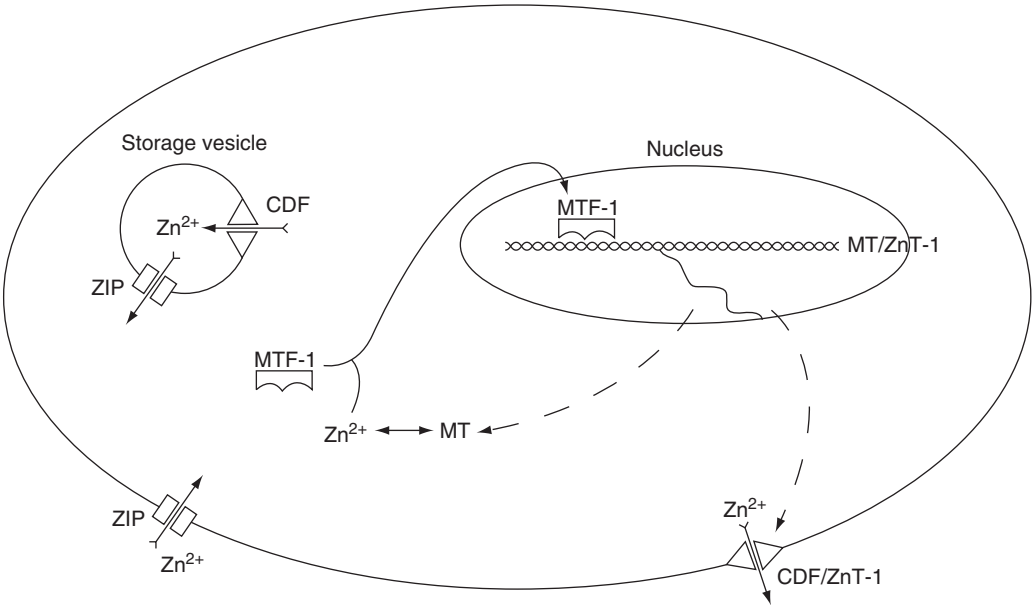

Figure 2 Cellular zinc homeostasis. Zinc is delivered to the cytoplasm from either the extracellular space or vesicles within the cell by members of the ZIP family of transporters. A rise in cellular zinc results in activation and nuclear translocation of MTF-1. In the nucleus, MTF-1 regulates transcription of a set of target genes including MT and ZnT-1. MT will bind zinc and ZnT-1 transports zinc out across the plasma membrane. MT may govern delivery of zinc to other proteins within the cell. Other members of the ZnT family transport zinc into vesicles.

Table 2 Examples of mammalian zinc-dependent enzymes

Enzyme	*Function*
RNA polymerase	Transcription, synthesis of mRNA
Carboxypeptidase A	Protein digestion in intestine
Protein kinase C	Signal transduction
Carbonic anhydrase	Respiration/buffering/hydration of CO_2
Cytochrome *c* oxidase	Respiration/electron transport chain
Alcohol dehydrogenase	Ethanol metabolism
Superoxide dismutase	Inactivation of free radicals
Nitric oxide synthase	Signaling, vasodilation
Angiotensin converting enzyme	Blood pressure regulation/activation of angiotensinogen

important class of zinc finger transcription factors is the steroid/thyroid receptor superfamily, responsible for mediating the biological response to a wide range of hormonal and metabolic signals, including retinoic acid and vitamin D. These all have nine conserved cysteine residues in the DNA binding region, eight of which are coordinated by two atoms of zinc. Loss of zinc from these sites would interrupt biological function but it is not clear that this ever happens in a physiological context. Gene expression profiling has been used to assess the genome-wide response to changing zinc availability in different tissues, including intestine, liver, and cells of the immune system. The gene products identified as zinc-sensitive by these approaches amount to approximately 5% of the expressed genes within a tissue. MTF-1 is likely to mediate some but not all of these changes and other transcription factors whose activity is dependent on zinc may soon be found.

Zinc Physiology

The enormous range of biochemical roles for zinc predicts broad effects on physiological function. The physiological roles of zinc may be further extended by secondary effects mediated by altered food intake and effects on the function of other nutrients. Although the physiological roles for zinc are well described, it is important to note that the connections between the biochemistry and physiology of zinc remain unclear. Thus the specific zinc-sensitive biochemical step leading to altered physiology is often unknown. The broad spread of zinc through the body at the organ, cellular and even protein levels suggests that the function of most systems is dependent on zinc. Its physiological roles become manifest under the circumstance of deficiency and that framework will be used to discuss principal functions here.

Growth

The requirement of zinc for growth of numerous organisms ranging from bacteria to humans is well established. Growth failure is an early consequence of zinc deficiency in experimental animals. Numerous processes seem to contribute to the growth failure. Experiments with animals have shown that zinc deficiency leads to a drop in food intake, though the use of pair-fed controls demonstrates clear effects of zinc deficiency beyond feeding behavior. Multiple effects of zinc deficiency on the somatotrophic axis have been demonstrated, notably a reduction in circulating concentrations of insulin-like growth factor-1 (IGF-1). Again, this is only part of the story because administering exogenous IGF-1 does not restore the growth failure of zinc deficiency. Growth of cultured cells

is dependent on media zinc. DNA synthesis is interrupted and production of thymidine kinase mRNA is diminished by removal of zinc, but again this is only a partial explanation. The IGF-1 signaling pathway within cells also seems to be affected. Zinc is also required for wound healing, presumably due to related processes.

Immune Function

The immune system is particularly sensitive to zinc deficiency. Lymphopenia and thymic atrophy are observed and both cell-mediated and antibody-mediated responses are reduced. As with growth, multiple mechanisms appear to be at play. In addition to generalized effects on DNA synthesis, zinc deficiency appears to induce apoptosis, resulting in a loss of B and T cell precursors within the bone marrow. Thymulin, a zinc-dependent enzyme that stimulates the development of T cells within the thymus, may be involved. Production of cytokines by mononuclear cells is also reduced by zinc deficiency. These effects can be of clinical significance. Infections occur more frequently in individuals with acrodermatitis enteropathica and reduced immune function is accompanied by zinc deficiency in several other conditions, including sickle cell anemia and various gastro–intestinal disorders.

Zinc has been used therapeutically in individuals with immune-compromised diseases. In the United States, zinc lozenges have become popular as a treatment for the common cold. Zinc supplementation has also been used as a supporting therapy for patients with HIV and AIDS, herpes simplex viruses, and hepatitis C infections. A shortening of cold duration, improved phagocytosis and increase in the number of Th cells, and a reduced frequency of opportunistic infections was observed in patients with HIV infection. However, results from controlled trials of zinc treatment with these diseases have been variable. Treatment effectiveness may depend on initial zinc status, with greater success being seen in individuals with marginal, undetected zinc deficiency.

Reproduction

The original description of zinc deficiency in humans included lack of pubertal development. Spermatogenesis is a zinc-dependent process. Seminal fluid is particularly rich in zinc and the sperm appears to accumulate zinc from this source before ejaculation. Zinc is also crucial for normal fetal development and deficiency leads to abnormalities in humans and animals. Maternal zinc deficiency has also been linked with pregnancy-associated morbidity, including preterm delivery.

Nervous System

The brain is one of the sites shown to be particularly sensitive to zinc deficiency during fetal development, with neural tube defects and other disorders being found. Although this work was performed with animals, a similar relationship appears likely with humans. Zinc is distributed throughout the brain, but greater concentrations are found within the hippocampus. Here a brain-specific transporter, ZnT-3, concentrates zinc in vesicles within glutamatergic neurons. It is co-secreted with the neurotransmitter and appears to serve as a modulator of neurotransmission. Very high concentrations of zinc ($>100\ \mu M$) are found within the synaptic cleft during this process. In addition, brain injury, resulting from ischemia or trauma causes the release of massive amounts of zinc, which is thought to be responsible for the resultant cell death.

Antioxidant Defense System

Although not an antioxidant itself, there are several ways in which zinc participates in the antioxidant defense system of the body, with important implications for health. It can bind to thiol groups in proteins, making them less susceptible to oxidation. By displacing redox-reactive metals such as iron and copper from both proteins and lipids it can reduce metal-induced hydroxyl radical formation and thus protect the macromolecules. Copper/zinc superoxide dismutase is an important antioxidant enzyme, which contains zinc and whose activity is impaired in the deficient state. Zinc depletion affects the activity of reactive oxygen species (ROS) and reactive nitrogen species (RNS) scavengers such as glutathione, ascorbic acid, uric acid, and α-tocopherol. The role of zinc in inducing MT has already been mentioned and this protein scavenges hydroxyl radicals. Increased oxidative stress results in the release of zinc from MT, presumably making it more available for other proteins. However, although zinc deficiency has been linked to greater oxidative stress, excess zinc can also lead to the same condition. So although MTs possess intrinsic antioxidant properties, there is evidence that in some circumstances, MTs may also serve as a source of injurious zinc release. Recent findings also suggest that nitrosative stress can act as a critical trigger for zinc mobilization. Nitric oxide (NO) or peroxy nitrite (–ONOO) interact with MT and promote zinc release both *in vitro* and *in vivo*.

The likelihood of increased oxidative stress under conditions of zinc deficiency suggests a potential anticarcinogenic role for this mineral. Indeed, zinc deficiency has been shown to result in DNA damage. The tumor suppressor gene, p53, which is frequently mutated in human cancers, is a zinc-containing transcription factor whose expression is also dependent on zinc. Dysregulation of cellular zinc homeostasis is linked not only to oxidative stress but also mitochondrial dysfunction and activation of apoptotic pathways.

Macronutrient Metabolism

Many of the enzymes of intermediary metabolism contain zinc and deficiency affects all macronutrients. Protein synthesis, as well as DNA and RNA synthesis requires zinc. Insulin is secreted from the pancreas and circulates in association with zinc. This secretion is diminished under conditions of deficiency, leading to impaired glucose metabolism. Lipid metabolism is also affected, with zinc deficiency associated with reductions in circulating high-density lipoprotein.

Human Zinc Deficiency

In addition to dietary inadequacy, there are several other routes that lead to zinc deficiency. Acrodermatitis entero-

pathica, the genetic disorder of zinc malabsorption has already been mentioned. Other, more generalized malabsorption syndromes (e.g., celiac disease) can also lead to zinc deficiency. Deficiency has also resulted from inappropriate intravenous feeding and use of chelation therapy. Children are likely to be particularly at risk for zinc deficiency, because of its involvement in growth.

Mild

Given the difficulty of assessing marginal impairments in zinc status, effects of deficiency can often only be verified by a response to treatment. Growth provides a good example of this. Children in Denver, Colorado who were of low height for their age showed increased growth rates in response to zinc supplementation, whereas zinc had no effect in children of normal height. In addition to growth, improvements in immune function, taste and smell acuity, and reproductive function have been noted with zinc supplementation.

Severe

Severe human zinc deficiency has been well characterized by the original descriptions in the Middle East and in patients with acrodermatitis enteropathica. The symptoms of mild deficiency are continued and exaggerated. Thus stunting can be extreme and is accompanied by delayed sexual maturation and impotence. Characteristic skin lesions are found, originating around the mouth and nose but becoming widespread as deficiency develops. Diarrhea is also present. Deficits in taste and smell are accompanied by anorexia and other behavioral changes, including increased irritability and impaired cognitive function. Eye pathologies similar to those seen with vitamin A deficiency are observed.

Zinc Toxicity

Toxicity of zinc from food sources has not been reported and seems unlikely because absorption is homeostatically regulated. Acute gastro–intestinal symptoms and headaches from ingestion of amounts approximately 10–20-fold higher than the recommended intakes have been described. Chronic ingestion of these large amounts has been shown to impair immune response and lipoprotein metabolism. However, the key danger from excessive zinc intake is reduced copper status. This is likely due to a zinc-induced blockage of copper absorption and in fact is clinically useful in individuals with Wilson's disease, a condition of copper toxicity. In the United States, an Upper Limit of 40 mg day^{-1} has been set for adults, based on the threat to copper status. The popularity of zinc lozenges for treatment of the common cold could lead to circumstances where this intake could be exceeded. Thus use of these treatments should be limited in duration.

Assessment

The prevalence of marginal zinc deficiency in human populations is unknown because of the lack of a good means for assessing zinc status. Measurement of plasma zinc is straightforward, but it does not serve as a reliable indicator of status. Plasma zinc is a quantitatively minor pool that can be easily influenced by minor shifts in tissue zinc. Plasma concentrations do not fall with dietary intake, except at very low intakes. Plasma zinc can also be affected by other factors unrelated to zinc status (e.g., time of day, stress, infection). Cellular components of blood can be assayed, but erythrocyte concentrations of zinc are maintained in deficient states and variable results have been found with leukocytes. Hair zinc concentrations may reflect available zinc but will also be dependent on rate of hair growth.

Several different zinc-dependent enzymes have been investigated as potential markers of zinc status but none has proved reliable. MT in blood cells has been suggested as a useful indicator of zinc status, either assayed at the protein of mRNA levels. MT expression is likely to be regulated by factors other than zinc and therefore may lack the specificity required of a good indicator. The gene array approaches that have recently been used to determine the global effects of zinc deficiency within a tissue would appear to offer hope for the identification of an appropriate functional marker of zinc status.

Recommended Intakes

In the absence of a reliable index of zinc status, both the US Food and Nutrition Board and the Food and Agriculture

Table 3 Recommended intakes for zinc

Age group		*US and Canadian recommended dietary allowance*	*FAO/WHO reference nutrient intake*		
			Bioavailabilty		
			High	*Moderate*	*Low*
Children (1–3 years)		3	2.4	4.1	8.3
Adolescents (14–18 years)	Female	9	4.3	7.2	14.4
	Male	11	5.1	8.6	17.1
Adults (>19 years)	Female	8	3.0	4.9	9.8
	Male	11	4.2	7.0	14.0
Pregnant women	3rd trimester	11	6.0	10.0	20.0
Lactating women	0–3 months	12	5.8	9.5	19.0

Organization/World Health Organization (FAO/WHO) expert committee used the factorial method to estimate human zinc requirements. Under this approach, routes of zinc loss from the body are estimated and summed. The requirement is then set as the amount of dietary zinc required to make up for these losses, making appropriate assumptions about bioavailability. For children, an additional amount is added to account for the zinc requirements for growth.

As shown in **Table 3**, the FAO/WHO give three sets of recommendations, depending on the zinc bioavailability of the diet. The US figures fall between those given for moderate and low availability diets. Both groups also set Upper Limits for intake, based largely on the risk of impairing copper status. These values are similar (40 mg US, 45 mg FAO/WHO, for adults).
